March 2015

Dear Ms Robison

## **PENROSE INQUIRY- FINAL REPORT**

On 12 January 2009, I was appointed by the then Cabinet Secretary for Health and Wellbeing, Nicola Sturgeon MSP, to hold a public inquiry into Hepatitis C/HIV acquired infection from NHS treatment in Scotland with blood and blood products.

I published a Preliminary Report in 2010. I now present to you my Final Report, which reflects the amount of work required to address the Terms of Reference.

Yours sincerely

**Rt Hon Lord Penrose**  
Chairman

## HOW TO READ THE FINAL REPORT

### *Availability of the Final Report*

The Final Report is published by the Inquiry in this printed version and on the Inquiry website <http://www.penroseinquiry.org.uk/>

In 2010 Lord Penrose published a Preliminary Report which is available at <http://www.penroseinquiry.org.uk/preliminary-report/>

### *The printed version*

The printed version of the Final Report consists of five volumes and an Executive Summary, which has also been printed as a separate document. There is also a DVD included in the box which holds these volumes as well as the Executive Summary, in both HTML and PDF versions.

### *The website version*

The Final Report is available in HTML and PDF versions. It is fully searchable.

### *Structure of the Final Report*

The Final Report consists of five volumes which represent five parts as set out in the contents page. The five parts cover: Patients' Experiences; Knowledge of HIV/AIDS and Hepatitis C; Blood and Blood Products; Donor Selection and Screening of Donated Blood; and Information to Patients.

The Executive Summary is printed as a separate document. There are conclusions within each chapter where appropriate. There is one recommendation which can be found at the end of Chapter 35, *An Investigation into the Steps Taken to Identify the Individuals who were Infected (Look-back)*.

### *Footnotes*

Footnotes in the Report include details of documents which provide the supporting evidence for points made in the text. The Inquiry assigned unique 10-character identifiers to every page in the evidence collected. These are in the form of three letters, followed by a three-digit number and a four-digit number, for example: SNB.002.1537. The reference for the document as a whole is simply the identifier of its first page. The three-letter prefix indicates the origin or nature of the document. 'SNB', for example, indicates a document from the archives of the SNBTS, and 'PEN' indicates a document or statement collected by the Inquiry during its own investigations. No significance attaches to this prefix in the context of the Final Report. In many cases the same document was recovered from several sources and the choice of which one to publish has been made on the basis of which was most complete or most readable.

In the electronic versions of the Report the document identifiers have been made into active links so that readers can click on the link and open the document to read the evidence for themselves.

Links are not included for some documents of a sensitive nature. These are generally the statements or medical records of patients and their family members. Some of the linked documents have also been redacted. This has been done to remove sensitive personal data or personal data that is not relevant to the Inquiry. The Inquiry's policy has been to leave as much text visible as possible so that the reader will understand the nature of the material that has been redacted.

The footnotes also contain references to the transcripts of the Inquiry's public hearings. These references give details of the witness, particularly where this may not be obvious from the text, the hearing day, and the page number or numbers where the relevant evidence appears. The transcripts are available on the Inquiry website and on the DVD attached to the printed version of the Report.

### ***Reference period***

The reference period for the Inquiry was 1 January 1974 to 1 September 1991. Some material necessarily pre- and post-dates this period in order to help fully understand the context in which events took place.

### ***Names and designations***

Each person mentioned in the Report is identified by his or her full name and title. Some of the people mentioned in the Report have had more than one designation during the reference period, a doctor, for example, becoming a professor. Their most recent title has generally been used in the text of the Report, except when quoting from contemporaneous documents.

The evidence given by patients and their relatives has been anonymised, except for the four named individuals whose deaths were investigated as part of the Terms of Reference: Reverend David Black, Mrs Eileen O'Hara, Mr Alexander Black Laing and Mr Victor Tamburrini. Those patients and relatives who gave oral evidence were given pseudonyms to protect their privacy.

## FOREWORD

When I was appointed as Chair of this Inquiry in January 2009, I did not know how many years the Inquiry would take, nor did the loyal members of my team who have remained with the task. Some inquiries relate to a single event. In others, as in this Inquiry, there are multiple factors that evolve over time. This creates a complexity that can only be resolved by critical analysis to define the particular areas for study, followed by ingathering and evaluating evidence with a view to reaching conclusions on matters of fact and opinion. This type of Inquiry can lead to an investigation of immense scope and so it has proved.

Both the duration and the cost of Inquiries are often matters of public concern, but until the evidence is ingathered, it is impossible to know the full scope of the task. Terms of reference only intimate the direction of the investigation: it is the evidence which dictates the necessary journey.

The terms of reference required a wide-ranging investigation into Hepatitis C and HIV/AIDS. That investigation involved people with bleeding disorders and those who had received blood transfusions: two very different groups, and those who had received blood transfusions are members of an extremely diverse group. With a timeframe of 1974 to 1991, the amount of material was vast.

The terms of reference also involved a requirement to investigate four specific deaths: Reverend David Black, Mrs Eileen O'Hara, Mr Alexander Black Laing and Mr Victor Tamburrini. The deaths of the Reverend Black and Mrs O'Hara played an important role in the genesis of the Inquiry as their relatives pursued the right to an independent investigation which ultimately led to this Inquiry being set up. Much effort has been expended in the investigation of the four deaths and it is to be hoped that their relatives obtain some comfort from this work.

It soon became apparent that the amount and complexity of the factual material alone for this Inquiry represented a significant challenge. I took the decision to write a Preliminary Report, setting out the factual narrative, which was published in September 2010. The Preliminary Report also contained the proposed topics for the hearings. The oral hearings commenced in March 2011. The Preliminary Report stood us in good stead and saved us a great deal of time during the hearings.

The oral hearings took place over 89 days and examined the controversial topics. They concluded in March 2012. We had over 13,000 pages of transcript, in addition to 200 witness statements and 120,000 documents in our database. The task of writing the Final Report has been demanding. Some topics were particularly challenging. More evidence had to be taken for the Statistics topic. The numbers of people affected are clearly important and this is reflected in the efforts made to ensure they were as accurate as possible.

Once the Final Report was in draft form in December 2013 there was a requirement under the Inquiries Act 2005 to issue warning letters to anyone subject to significant or explicit criticism. This included not just criticisms made by the Inquiry but also those made of individuals in evidence, if repeated in the Report. Again the warning letter process constitutes unknown territory as the impact of the responses cannot be known until they

are seen. As currently framed, the statutory requirement is far-reaching, with inevitable consequences for the time required to complete the Report.

The Final Report is long because of the amount of evidence and the need to understand the development of the diseases and their impact not just on people with bleeding disorders but also on anyone who had become infected with Hepatitis C or HIV through a blood transfusion.

Much of the comment made over the years on the topics discussed in the Final Report has reflected strongly-held beliefs. Some commentators believe that more could have been done to prevent infection in particular groups of patients. Careful consideration of the evidence has, however, revealed few respects in which matters could or should have been handled differently.

One area where it is concluded that more could have been done is in the delay in the introduction of screening for Hepatitis C. In relation to AIDS, it appeared to the Inquiry that, once the risk had emerged, all that could reasonably be done, was done. When actions in Scotland were subjected to international comparison, they held up well.

This was always going to be an Inquiry about what happened in the past as opposed to a commentary on current practice with recommendations for change. Indeed there is only one recommendation – the need to make further efforts to assist anyone who received a blood transfusion before September 1991 and who has not had a test for Hepatitis C. The Scottish Government must take action to address this.

The length of time which had passed since the events addressed by this Inquiry was unusually long. We were constantly aware of the need to understand the conditions prevailing at the time and not to judge events by today's standards. This was found to be true especially in relation to the doctor-patient relationship which was acknowledged to be paternalistic at the beginning of the period. There was a great deal of dissatisfaction on the part of patients about the information provided to them. This was found to be a combination of genuine lack of information as the understanding of the conditions developed, and the nature of the relationship in which doctors were not used to sharing all information available with patients as they do today.

Much of this Inquiry has been about the adverse consequences experienced by those who were infected by HIV/AIDS and or Hepatitis C. The impact on their lives and those of their loved ones has often been devastating, as set out in the Report. I would also comment on the often forgotten suffering of clinical staff, who were to discover that the treatments they thought were beneficial to patients actually caused them to become infected with life-threatening conditions. This is the stuff of nightmares, and they too have suffered, especially when accused of knowing or deliberate attempts to harm patients. One doctor eloquently described his experience of prescribing the new concentrate products which offered so much to patients with haemophilia only to discover the threat of AIDS as, 'waves of hope, followed by waves of despair'. Patients and doctors shared this experience.

The work of the Inquiry could not have been carried without the support and active participation of the administrative staff, lawyers and paralegals. I am grateful to the Medical Assessor to the Inquiry, Professor Oliver James, Emeritus Professor of Medicine, University of Newcastle, for his advice and guidance throughout the process.

Laura Dunlop, QC, worked with diligence and dedication. Maria McCann and her team provided the administrative support without which the process would have been impossible. The individual members of both teams are listed in Appendix 2. I wish to record my unqualified thanks and admiration for their work, sometimes carried out in trying circumstances.

Finally, I would like to thank all those who gave evidence to the Inquiry. The courage of the patients and relatives is manifest within the relevant chapters in the Final Report. I also pay tribute to those patients who gave evidence and who have sadly died during the course of the Inquiry. I offer my sincere condolences to their loved ones.

The Right Honourable Lord Penrose

# CHAPTER 1

## INTRODUCTION

**1.1** This is the Final Report of the Inquiry into the transmission of blood-borne viruses to people in Scotland in the course of medical treatment provided by the NHS. The viruses, HIV and Hepatitis C, cause life-threatening illness. Some of those who became ill following infection with one or both of these viruses died as a result, and others continue to live with serious ill-health. Why and how that occurred has been investigated in depth by the Inquiry and the results of that investigation are set out in full in this Report. A summary version of the Report is available separately.

### **Origins of the Inquiry**

**1.2** On 18 April 2006, the Health Committee of the Scottish Parliament called for a Public Inquiry into the infection of people with Hepatitis C from NHS treatment. The then Scottish Executive decided not to hold an Inquiry, but the Scottish National Party made a commitment in its 2007 manifesto to hold such an Inquiry if elected to form the government in Scotland.

**1.3** Separately, the personal representatives of Reverend David Black and Mrs Eileen O'Hara, two individuals who appeared to have acquired Hepatitis C from NHS treatment with blood or blood products in Scotland and who had since died, raised proceedings in the Court of Session to challenge decisions not to conduct investigations into those deaths. The challenges were successful, the court taking the view that, under Article 2 of the European Convention on Human Rights, the applicants were entitled to an independent Inquiry into the deaths of their relatives.

**1.4** On 23 April 2008, the then Deputy First Minister and Cabinet Secretary for Health and Wellbeing, Nicola Sturgeon MSP, announced to the Scottish Parliament that there would be a judicially led Public Inquiry, under section 28 of the Inquiries Act 2005, into the transmission of Hepatitis C and HIV from blood and blood products to National Health Service patients in Scotland. She informed Parliament that the Rt. Hon. Lady Cosgrove would chair the Inquiry. Lady Cosgrove subsequently withdrew for family reasons. The Inquiry was set up as the Penrose Inquiry on 13 January 2009 with 12 Terms of Reference.

### **Terms of Reference**

**1.5** The Terms of Reference required the Inquiry to investigate the deaths of named individuals who were thought to have acquired Hepatitis C from treatment with blood or blood products and, more generally, to investigate how patients in Scotland acquired HIV or Hepatitis C from blood or blood products, and the consequences of such infection. An amendment to the Terms of Reference was announced in November 2009 to include three additional deaths which were to be investigated and a further amendment to them was made in February 2011 to remove one of those individuals from the investigation. The Terms of Reference, as amended, are as follows:

1. To investigate the systems in place in Scotland for the collection, treatment, licensing, testing, preparation for supply and supply for use by the NHS of blood and blood products with particular reference to the risks of transmission of the Hepatitis C virus and HIV to patients treated by the

- NHS in Scotland, including the role of government in regulation and setting guidelines and standards.
2. To investigate the systems in place for informing patients treated by the NHS in Scotland of the risks associated with the use in their treatment of blood or blood products, with particular reference to the risks of infection with the Hepatitis C virus and HIV.
  3. To investigate the systems in place in Scotland for obtaining consent from, and testing for infection with Hepatitis C and HIV, patients treated with blood or blood products, and informing any patients found to be so infected.
  4. To investigate the systems for recording and monitoring the numbers of NHS patients in Scotland treated with blood and blood products, with particular reference to the numbers exposed to risk of infection with the Hepatitis C virus and HIV and the numbers contracting either or both such infections as a consequence of such treatment.
  5. To examine the circumstances generally in which patients treated by the NHS in Scotland became infected with Hepatitis C, HIV, or both through the use of blood or blood products in the course of their treatment, taking account of the development of scientific and clinical understanding and evidence internationally.
  6. To investigate the deaths of Reverend David Black, Mrs Eileen O'Hara, Alexander Black Laing and Victor Tamburrini, with particular reference to the circumstances in which they became infected with the Hepatitis C virus, HIV or both.
  7. To investigate the steps taken by those involved in, and those responsible for, the NHS in Scotland, including NHS Boards and the Scottish National Blood Transfusion Service (SNBTS), their officers and employees and associated agencies, once Hepatitis C and HIV were identified, to trace individuals who might have become infected with one or both of them as a result of receiving blood or blood products; and to identify any other or further steps that might reasonably have been taken to trace such individuals.
  8. To investigate the steps taken by those involved in, and those responsible for, the NHS in Scotland including NHS Boards and SNBTS, their officers and employees and associated agencies, to prevent the provision of infected blood and blood products.
  9. To investigate the steps taken by those involved in, and those responsible for, the NHS in Scotland including NHS Boards and the SNBTS, their officers, employees and associated agencies to inform individuals who might have received infected blood or blood products of the risks associated with their treatment for themselves and their families; and to offer treatment to any individual at risk, and to identify any other or further steps that might reasonably have been taken to inform and to treat such individuals.
  10. To examine any particular adverse consequences for patients treated by the NHS in Scotland and their families of infection through blood and blood products with Hepatitis C and HIV, including the treatment offered.

11. To identify any lessons and implications for the future, and make recommendations.
12. To report as soon as practicable.

**1.6** The period scrutinised by the Inquiry began on 1 January 1974, although in many respects, it was necessary to make some study of earlier events in order to provide context for the principal examination. The period ended on 1 September 1991, when screening of donated blood for the Hepatitis C virus was introduced throughout the UK. As occurred with the commencement date, it was not possible to adhere to a fixed point for termination of the period investigated. Some parts of the Report therefore make reference to events after 1991, in order to explain the outcome in relation to specific aspects of the investigation.

### **Work of the Inquiry**

**1.7** The Inquiry discharged its remit in four stages: gathering information and documents and familiarisation of the Inquiry Team with the issues; preparing, and publishing in September 2010, a Preliminary Report setting out the evidential background to the matters covered in the Terms of Reference; hearings in relation to defined topics; and the writing and publication of this Final Report. It was recognised that additional factual material was likely to emerge during the hearings stage of the Inquiry's work, and so it proved; in consequence of this, a fuller factual background is set out in this Report, with references to the Preliminary Report where appropriate.

**1.8** The selection of topics for oral hearings was made following research carried out by the Inquiry Team up to, and including, the writing of the Preliminary Report. The process whereby a virus was transmitted from donor to recipient offered several stages at which infection could have been prevented: selection of blood donors; screening of donations for viral infection; treatment of blood products (although not whole blood) to destroy viruses present; and the approach adopted to use of blood and blood products in the treatment of individuals. The extent of information communicated to patients about the hazards of treatment, primarily before treatment was given but also after it had occurred, was also an important part of the story. The topics selected for exploration at hearings reflected all these aspects. They are listed in Appendix 1.

### **Oral hearings**

**1.9** The hearings took place between 8 March 2011 and 30 March 2012. The presentation of evidence was led by the team of Counsel to the Inquiry. Counsel representing (i) patients, families and the Haemophilia Society; (ii) National Health Service interests and (iii) the Scottish Government were also present throughout, and able to question witnesses. Evidence was led from 67 witnesses, and 120,000 documents were introduced. Submissions were made by Counsel during the hearings, on various matters, and closing submissions were presented by those listed in (i) to (iii) above.

**1.10** It will be obvious that the period into which the Inquiry was conducting its examination was more than 20 years ago. This inevitably affected the quality of recollections. Some key witnesses had died. On the other hand, the database assembled by the Inquiry held many thousands of documents, and it was frequently possible to reconstruct events from a combination of written material and the testimony of those involved. Where the Inquiry has not found it possible to resolve questions of fact, that is stated in the Report. These instances are few.

**1.11** The approach adopted, of examining individual topics, meant that certain key NHS personnel had to attend to give evidence on more than one occasion. Two clinicians attended on 10 occasions each. Every witness who testified, whether physician or lay person, will have experienced inconvenience and a degree of stress. The Inquiry was and is aware of this, and is grateful for the contribution made by all those concerned.

### **Warning letters**

**1.12** During the final stage of the Inquiry's work, it was necessary to prepare and send warning letters in accordance with Rule 12 of the Inquiries (Scotland) Rules 2007. Rule 12(7) provides:

The inquiry ... must not include any significant or explicit criticism of a person in the report ... unless –

- (a) the chairman has sent that person a warning letter; and
- (b) the person has been given a reasonable opportunity to respond to the warning letter.

**1.13** To comply with this Rule, it was necessary to send 103 warning letters. One hundred replies were received, running to over 1000 pages of material. The points made in these responses were considered by the Chairman and his team and, in some instances, changes were made to draft text of the Report in order to reflect points that were considered well-founded.

### **Structure of Final Report**

#### ***Part one***

**1.14** The first part of the Report gives an indication of the patients primarily at risk of viral infection from blood and blood products, and covers the effects of Hepatitis C or AIDS, or both conditions, and their treatment, on patients and their families. As Term of Reference 4 required the Inquiry to investigate the numbers of patients exposed to the risk of contracting either or both conditions through treatment with blood and blood products and the numbers who actually contracted the conditions, Chapter 3 entitled *Statistics* provides the results of that investigation. Part one also contains a chapter concerned with the investigation of the deaths of certain named individuals which, in consequence of Term of Reference 6, the Inquiry was specifically required to investigate (see Chapter 7).

#### ***Part two***

**1.15** The second part of the Report deals with knowledge, past and present, of HIV/AIDS, covering its aetiology, geographical spread, prevalence, and the response to it in clinical practice. This part of the Report is also concerned with knowledge of viral hepatitis, as at the beginning of the reference period and from 1975 until the present day.

#### ***Part three***

**1.16** The third part of the Report provides information on blood collection and the production of blood products, including details of the management of such activities and the facilities relating to collection and production. It also provides information on haemophilia therapy, including the use of blood products, up until 1987. Finally, it contains chapters on the viral inactivation of blood products for such therapy up until 1987.

### *Part four*

**1.17** The fourth part of the Report considers the discovery of HIV and the development of screening tests for it; screening of donated blood for, respectively, Hepatitis B, C and HIV; donor selection; and surrogate testing of donated blood for what was then known as non-A, non-B Hepatitis, later recognised as largely due to Hepatitis C.

### *Part five*

**1.18** The fifth part of the Report is devoted to a consideration of the information given to, or withheld from, patients by the medical profession, and the ethical principles governing the provision of, or withholding of, such information at the relevant time and currently. The relevant information concerned, primarily, the risks of HIV/AIDS and Hepatitis C and patients' test results. This section of the Report also covers 'look-back', the Inquiry's investigation into the steps taken to identify individuals infected by HCV as a result of treatment with blood donated prior to HCV screening. A glossary is also contained in this part of the Report.

### *Appendices*

**1.19** The Report has five appendices. Appendix 1 details the processes followed by the Inquiry, including the governing law and the specific procedures adopted, and outlines the Core Participants and how they were selected. Appendix 2 covers Inquiry organisation and administration, including the provision of IT for the preparatory phase and for the hearings, and the processing of documents. Appendix 3 details the individuals and organisations which were designated as Core Participant. Appendix 4 lists the witnesses who gave evidence at the oral hearings. Appendix 5 gives details of all the Inquiry Procedure Directions, Guidance Notes and Restriction Orders which were issued during the course of the Inquiry.

### **Recommendation**

**1.20** There were four groups of people in Scotland affected by this tragedy: those who acquired the Hepatitis C virus (HCV) from blood transfusion; those who acquired HCV from treatment for bleeding disorders; those who acquired HIV from blood transfusion; and those who acquired HIV from treatment for bleeding disorders. As the Report explains, the risks which materialised in relation to individuals in these groups do not now exist in the same way. Donated blood is screened for HIV and HCV, and blood products used in the treatment of bleeding disorders are artificially synthesised and do not pose a risk of transmission of blood-borne viruses.

**1.21** Owing to the significant changes which have taken place, it was not necessary for the Inquiry to identify measures required to prevent recurrence of infection with HIV and HCV through blood transfusion or therapy for bleeding disorders. The primary focus for the Inquiry's work was retrospective: posing and answering questions relating to how infection in the reference period occurred, and whether steps which might have prevented these events were available and were taken timeously. Answering these questions is of paramount importance to those who acquired infection, and to those who lost loved ones.

**1.22** In conclusion, there is one respect in which the Inquiry has identified action still required to deal with past transmission of HCV. In the look-back chapter (see Chapter 35), the Inquiry sets out its recommendation that people who received a blood transfusion in the period before screening of donated blood for HCV was introduced, on 1 September 1991, but who have never been tested for HCV, should now be offered such a test.

## CHAPTER 2

### PATIENTS AT RISK

#### Introduction

**2.1** NHS patients with bleeding disorders and medical and surgical patients requiring transfusion of blood or blood components formed small cohorts only of the total UK populations exposed to risk of infection with Hepatitis C and HIV/AIDS. Reports from 2014 estimated that there were 214,000 chronically infected individuals with HCV, and 107,800 with HIV/AIDS in the UK.<sup>1</sup> The numbers of NHS patients infected in Scotland are discussed in Chapter 3, *Statistics*. In summary, around 2500 individuals are thought to have been infected with HCV by transfusion and a small number of transfusion patients, estimated at 18 minimum, with HIV. 478 bleeding disorder patients are thought to have been infected with HCV, and 60 with HIV.

**2.2** As this Report will discuss, there was research of unprecedented intensity into the aetiology and natural history of AIDS and into the development of forms of therapy for infected individuals, resulting in the effective treatment of HIV and control of its progression to AIDS. AIDS appeared to be a genuinely new disease when it was first reported and commitment by governments, public sector scientists and the pharmaceutical industry in response to it achieved these results in a very short time, reflecting the common perception that the disease threatened to achieve pandemic proportions, with high mortality. HCV proved to be a more intractable problem but, in that context also, the efforts of researchers led to the identification of enough of the genetic structure of the virus to allow for the development of tests for infection, a developed understanding of the natural history of the disease and, in due course, treatment of those infected.

**2.3** The NHS patients with whom this Report is primarily concerned benefited from these scientific and technological developments, as did other groups at risk, and it has been necessary to discuss them at some length in later chapters of this Report. The common element affecting the various groups exposed to risk was that infection was transmitted by blood. That applied as much to intravenous drug users as to blood disorder patients receiving blood component or blood product therapy. It is important to bear in mind that the medical and other scientists conducting research and developing technology for identifying infection in blood, for example, were often concerned with the interests of the larger populations at risk and were not narrowly focused on blood disorder and transfusion patients.

**2.4** In this chapter, the focus is on the groups of people who were potentially at risk from infection and the procedures that gave rise to risk. The patient groups exposed to risk were:

- Patients receiving transfusions of blood or blood components in the course of medical care or surgical procedures.
- Patients with bleeding disorders, such as haemophilia, who received whole blood, blood components and products manufactured from human plasma in the course of therapy for their primary disease.

---

<sup>1</sup> <https://www.gov.uk/government/statistics/hiv-in-the-united-kingdom> & <https://www.gov.uk/government/publications/hepatitis-c-in-the-uk>

**2.5** The topic was discussed in Chapter 3 of the Preliminary Report. Since the writing of that chapter, subsequent investigation and the oral evidence led at the public hearings, particularly from experts in the field, have added significantly to the Inquiry's understanding both of the scope of the risks and of the impact of infection on individuals and on their families. The account which follows is therefore fuller than the account in the Preliminary Report and varies from it in part.

**2.6** This chapter discusses, with the benefit of hindsight, the causes of risk and the practices that gave rise to risk generally, without reference to a time line of developing knowledge. The chronology of the developing knowledge of individual diseases is discussed later.<sup>2</sup>

## **Patients receiving transfusions of blood and blood components**

### *Historical overview*

**2.7** As noted in the Preliminary Report<sup>3</sup>, safe transfusion, in the broadest sense, is a relatively modern procedure. Dr Derek Norfolk, a Consultant Haematologist practising mainly in Leeds, provided oral evidence and a witness statement on the use of blood components in clinical medicine.<sup>4</sup> Dr Norfolk developed a particular interest in blood components and patient safety and, in 2006, took up a joint appointment with NHS Blood and Transplant and Leeds Teaching Hospitals NHS Trust. He is a member of the National Blood Transfusion Committee of the Chief Medical Officer for England and Wales. In the last decade he has written frequently on transfusion medicine.<sup>5</sup>

**2.8** Dr Norfolk gave an insight into the hazards of nineteenth century transfusion practice:

Following early, but often ill-fated, attempts at blood transfusion in the 17th century, the first well-documented successes were those of the Edinburgh and London obstetrician Dr James Blundell ... who '... appalled at my own helplessness at combating fatal haemorrhage during delivery...', reported 10 direct donor to patient transfusions between 1819 and 1829. However, the equipment was primitive, the volumes transfused were small and, with no knowledge of blood groups, serious reactions were common.<sup>6</sup>

**2.9** Direct transfusion involved connecting the donor and the recipient by a tube as they lay or sat together. In obstetric practice, the donor was usually the husband of a woman bleeding in childbirth.<sup>7</sup> The procedure was inherently hazardous and, in 1873, the Obstetrical Society of London concluded that transfusion should be used only as a last resort.<sup>8</sup> Real progress began only in the twentieth century.

**2.10** Karl Landsteiner, a biologist and physician working in Vienna, discovered the ABO blood group system in 1901, although it took some time before his discovery began to influence clinical practice.<sup>9</sup> Transfusion using donor blood advanced little until it was introduced into military practice towards the end of the First World War, although it was not used very much in civilian practice for another two decades. It was only during the

<sup>8</sup> Dr Norfolk's Report [PEN.010.0048]

<sup>9</sup> Dr Norfolk – Day 7, page 60. (Landsteiner was also, with Alexander S Wiener, responsible for the discovery of the Rhesus factor in 1937. These two discoveries – ABO and Rhesus – were essential to the possibility of blood transfusion as currently practiced.)

Second World War that voluntary blood donation was established generally in the UK. It appears that war has always been a major promoter of advances in transfusion technology and medicine and that continues in modern conflict zones.<sup>10</sup>

**2.11** Until transfusion in medical and surgical practice came into general use, the risk of transmission of viral infection was relatively low. There were other risks associated with blood transfusion, such as haemolysis (the breakdown of red blood cells), that tended to have more immediate consequences.

### *Blood transfusion in the reference period*

**2.12** In the middle of the twentieth century, the relatively high risk of haemolysis was reduced by the development of sophisticated blood matching technology. With that reduced risk, however, the transmission of viral infection became more significant as transfusion became more common and as clinical practice tended towards the use of blood components. The use of continuous flow techniques (apheresis) that return unwanted components to the donor and collect only targeted components ensured an approach to collecting donations that was safer for the donor and clinically and economically more sensible,<sup>11</sup> although it appears that the procedure was not extensively used over much of the reference period for this Inquiry.<sup>12</sup> That change in technology did not, in any event, have a direct impact on the risk of transmission of any infection in the donor's blood, since such infections affected the component also.

**2.13** A change of practice that did have an impact on the spread of risk was the separation of whole blood into its major components after donation.<sup>13</sup> The major components are red cells, white cells, platelets and plasma. Plasma is the straw-coloured liquid portion of blood. It contains, in suspension, proteins, such as albumin, antibodies and clotting factors, as well as hormones, fats and dissolved salts and gases.<sup>14</sup> Blood cells are suspended in plasma and can therefore be removed by centrifugation.<sup>15</sup> The separation and use of blood components served a number of purposes. Most patients needing transfusion require the replacement of only one particular blood component, such as red cells for anaemia. Separation into components allows several patients to benefit from a single donation. Storage requirements vary: red cells survive for at least 35 days at 4°C while platelets are damaged by refrigeration and have to be stored at room temperature. Separation allows the different requirements of safe storage to be accommodated. The practice made and continues to make clinical and economic sense.<sup>16</sup>

**2.14** All of these blood components were in use in Scotland throughout the reference period and each of them, the red cell units and platelet and plasma preparations used in clinical practice, may transmit infection. Red cells contain a small amount of plasma and platelets are suspended in plasma and even the relatively small amount of plasma involved would be capable of transmitting a viral infection.<sup>17</sup> As the practice of component use

---

<sup>10</sup> Dr Norfolk's Report [PEN.010.0048]

<sup>11</sup> Dr Norfolk – Day 7, page 64

<sup>12</sup> The reference period for this Inquiry begins on 1 January 1974, the date selected by the Cabinet Secretary for Health and Wellbeing at the outset of the Inquiry's work. There is no specified end-date for the reference period, it having been necessary to consider aspects of the Terms of Reference which continue to operate until the present day.

<sup>13</sup> The use of blood components was promoted by SNBTS from the beginning of the 1970s: see Chapter 17, *Blood and Blood Products Management*, paragraph 17.55.

<sup>14</sup> Dr Foster's paper [PEN.013.1125] at 1127

<sup>15</sup> Dr Norfolk's Report [PEN.010.0048], section 2 from 0049 and section 3.3.1 from 0051.

<sup>16</sup> Ibid [PEN.010.0048] at 0049

<sup>17</sup> Dr Norfolk – Day 7, pages 65–66

increased during the reference period, the numbers of recipients correspondingly at risk of transmission of infection from a single donor increased.

**2.15** The clinical application of blood and blood components has changed over the reference period and it will be possible to identify only significant points of transition towards modern practice. The Preliminary Report traced the growing use of red cell concentrates between 1975 and 1990.<sup>18</sup> Between 1975 and 1981 use increased threefold. Growth continued until 1989, by which point it had reached almost five times its 1975 level. Simple partition into the components most frequently used in clinical practice, without further virucidal treatment, would not have increased the risk of introducing infected blood into the system: the proportion of blood donors who were carriers of infection would not have been altered by the sub-division of donations into blood components. On the other hand, the components of a single infected donation had the capacity to infect more patients than transfusion of the donation as whole blood from one individual donor to a single recipient, and risk overall increased.<sup>19</sup> In that sense, changing clinical practice did change risk.

### *Red cell transfusions*

**2.16** The clearest indication for a red cell transfusion is in patients who have dangerous bleeding after trauma, surgery or childbirth. In those cases, the urgent transfusion of red cells may be required. The body replaces platelets and plasma much more quickly than red cells and the production of red cells may fall short of what is required to replace those lost or consumed in coagulation.<sup>20</sup> In many of these cases transfusion of red cells is essential to maintain life and the prompt replacement of red cells can be life-saving in some cases.<sup>21</sup>

**2.17** There are many causes of anaemia (decreased red cells in the blood), not associated with bleeding, that require medical intervention. The bone marrow may fail to produce enough healthy red cells or the cells produced may have a shortened lifespan in circulation. Genetic diseases such as thalassaemia and sickle cell disease, a lack of essential nutrients such as iron or vitamin B12, serious bone marrow diseases such as leukaemia or aplastic anaemia and anaemia due to inflammation or cancer, all require transfusion of red cells.

**2.18** Particular types of patient receive more transfusions than others. Recent studies have shown that, in the case of red cell transfusions, there is an early peak in sick newborn babies, mainly in the first month of life. In the 20–40 age group red cell transfusion is more common in females than in males because of obstetric and gynaecological indications. All studies have shown that the transfusion of red cells increases sharply over the age of 60: the median age of patients receiving red cell transfusion in one study was 69 years.<sup>22</sup> In a later study, carried out in 2004, it was found that 62% of all red cell transfusions were received by medical patients; 33% by surgical patients; and 5% by obstetric patients. The most common surgical indications were orthopaedic surgery, gastrointestinal and liver surgery and cardiac surgery (16.7% in aggregate). A further 5.9% of red cell transfusions were used in treating trauma patients. These percentages are not absolute, as between

<sup>18</sup> Preliminary Report, paragraph 5.52 and Figure 1.

<sup>19</sup> An extreme example was reported from Italy where a single donation divided into 31 aliquots and administered as mini-transfusions infected 18 neonatal patients with Hepatitis. Castiraghi *et al* 'Long term outcome (35 years) of hepatitis C after acquisition of infection through mini transfusions of blood given at birth', *Hepatology* 2004 (39:90–96) [LIT.001.4027] See Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.70

<sup>20</sup> Dr Norfolk's Report [PEN.010.0048] at 0051

<sup>21</sup> *Ibid* [PEN.010.0048] at 0050

<sup>22</sup> The Epidemiological and Survival of Transfusion Recipients (EASTR) study discussed in Dr Norfolk's Report [PEN.010.0048] at 0053

2000 and 2004 the number of red cell transfusions used in surgery fell by around 25% despite significant increases in orthopaedic and cardiac surgery. The percentages given do, however, provide an indication of the order of magnitude of the use of the component.<sup>23</sup>

**2.19** In modern practice, red cells remain the most commonly transfused blood component.<sup>24</sup> Improvements in surgical and obstetric techniques in western countries have reduced the use of blood for surgery and during childbirth. Some orthopaedic procedures, such as knee replacements, involve a lot of bleeding during surgery. Modern clinical practice, however, uses technology to re-infuse the patient's own blood, collected during an operation by 'cell saving' techniques, so reducing dependence on transfusion.<sup>25</sup> When liver transplantation was first carried out it was not uncommon for patients to need massive blood transfusions, up to 50 or even 100 units of red cells, to support the patient during the procedure. Re-infusing the patient's own blood has reduced transfusion in many cases to two or three units of blood.<sup>26</sup> With these new techniques, such residual risk of the transmission of infections, like the Hepatitis C virus (HCV) and HIV, as subsists notwithstanding modern screening techniques, was reduced. The emerging risks of transmission of as-yet unidentified viruses were also reduced. The use of transfusion in surgery has now reduced to the extent that in most modern hospitals more than half of all red cells are transfused to medical patients (those not undergoing surgery), typically patients with anaemia.<sup>27</sup>

### *Platelet transfusions*

**2.20** Platelet transfusion became readily available in the UK from the late 1970s.<sup>28</sup> Significant quantities were produced by Regional Transfusion Centres (RTCs) in Scotland before the beginning of the reference period. Production increased after the mid-1970s. Patients with very low platelet counts are at increased risk of bleeding and, at extremely low levels, may die of serious internal bleeding. Low platelet counts (thrombocytopenia) are a feature of bone marrow diseases such as leukaemia and are often a temporary effect of cancer chemotherapy or cardiac bypass surgery. The condition is also commonly seen in patients in intensive care and in sick newborn babies, often caused by serious illness. In modern practice prophylactic platelet transfusions are used to try to avoid bleeding.<sup>29</sup> The pattern of usage of platelets is broadly similar to the pattern of red cell usage.<sup>30</sup>

### *Other components and products*

**2.21** Clinical use of plasma and products derived from plasma predates the reference period. Plasma for clinical use is separated from the cellular components of blood soon after collection and quickly frozen as fresh frozen plasma (FFP). The pattern of usage of FFP is broadly similar to the pattern of red cell usage.<sup>31</sup> The main use of FFP is in the treatment of patients who are bleeding as a result of major tissue trauma, as occurs in road traffic and other serious accidents, military trauma or obstetric complications, when the natural clotting system cannot produce new clotting factors fast enough to replace those consumed in clotting. This condition, disseminated intravascular coagulation, is also

<sup>31</sup> Ibid [PEN.010.0048] at 0056

a potentially life-threatening complication of many acute illnesses, and is commonly seen in very sick newborn babies and in patients with cirrhosis.<sup>32</sup>

**2.22** Current usage of all components and products reflects major changes over time. For example, cryoprecipitate, a derivative of FFP initially developed as a source of Factor VIII<sup>33</sup> for the treatment of clotting factor deficiencies, has been used over the last two decades primarily as a source of fibrinogen for the treatment of patients with major haemorrhage.<sup>34</sup>

## Patients with Bleeding Disorders

### *Patients at risk*

**2.23** Individuals with haemophilia and related coagulation disorders who received whole blood, blood components and blood products were at risk of transmission of infection by treatment.<sup>35</sup> Haemophilia and its treatment were discussed in detail at paragraphs 3.9–3.82 of the preliminary report, and readers are referred to that discussion for more background on the condition and its effects. There is a broad relationship between the risk of transfusion-related transmission of viral infection and the severity of the patient's underlying condition. There are necessary qualifications of this statement which will emerge in the course of this chapter, but current classification criteria are inevitably part of the context in which risk to these patients has to be considered.

**2.24** The World Federation of Haemophilia has graded the severity of Haemophilia A and B according to the quantity of clotting factor (Factor VIII for Haemophilia A and Factor IX for Haemophilia B) in a given patient's blood,<sup>36</sup> as follows:

- <1 international unit per decilitre (iu/dl) - Severe
- 1 – 5 (iu/dl) - Moderate
- 5 – 50 (iu/dl) - Mild

**2.25** Dr Brian Colvin, until 2007 Director of the Haemophilia Centre at Barts and The London Hospital, observed, however, that diagnosis at the edges of normality can be difficult.<sup>37</sup>

**2.26** The normal range of Factor VIII is between 50 and 150 iu/dl. In practical terms, at below 50 iu/dl a degree of abnormal bleeding is found in haemophilia patients and in women who are carriers of haemophilia. Below this level people can have significant clinical problems at times of dentistry or surgery or following trauma.<sup>38</sup> There are other classifications, for example The International Society on Thrombosis and Haemostasis defines the upper limit of mild haemophilia at 30 iu/dl,<sup>39</sup> but for NHS purposes 50iu/dl is accepted.<sup>40</sup>

<sup>32</sup> Ibid [PEN.010.0048] at 0052

<sup>33</sup> Factor VIII is a protein essential for the normal clotting of blood. Haemophilia A is a deficiency of this 'clotting factor'.

<sup>34</sup> Dr Norfolk – Day 7, page 73

<sup>35</sup> Preliminary Report, paragraph 3.1

<sup>36</sup> Dr Colvin – Day 2, page 80; Witness Statement of Dr Winter [PEN.015.0292]

<sup>37</sup> Ibid, page 82

<sup>38</sup> Dr Winter – Day 15, pages 58–59

<sup>39</sup> Ibid, pages 69–70

<sup>40</sup> Some NHS clinicians continue to prefer older formulations, while conforming to the official policy: see, for example, Professor Ludlam's Witness Statement [PEN.015.0385] at 0388 and Professor Ludlam's evidence on Day 18, Pages 23–25. For present purposes it is not necessary to resolve these differences.

**2.27** Traditionally, the classification of a patient's haemophilia as mild, moderate or severe has been based on the level of Factor VIII or Factor IX found on assay using the technology available at the time. Some patients who have extremely low levels of Factor VIII, including some who do not produce Factor VIII at all, do not bleed excessively, however, and therefore do not require replacement therapy as often as might be expected, or in a few cases do not require it at all. In some cases it has been discovered that the patient has acquired another gene that develops clotting. Dr Mark Winter, Kent and Canterbury Hospital, described the case of a child who had acquired a severe haemophilia gene from his mother and a thrombosis gene from his father. The clinical result was that, although the child had no natural Factor VIII, his father's thrombosis tendency made his bleeding less than expected. Clinically, he behaved like a patient with mild haemophilia.<sup>41</sup>

**2.28** Quite apart from such exceptional cases, the level of Factor VIII or Factor IX in an individual case is not determinative of exposure to risk of bleeding: the level of physical activity of the patient is a much more common indicator.<sup>42</sup>

**2.29** It is now possible to precisely identify the genetic defect responsible for haemophilia.<sup>43</sup> Generally speaking, haemophilia breeds true within a family: those who are affected within the family tend to be affected to a similar degree. However, people's characters do differ and individuals of a sedentary disposition are less likely to bleed than those who are physically active. Bleeding in the first years of life is a strong determinant of subsequent bleeding. An active child who falls off his bike from time to time is more likely to have trouble than a sibling who sits at home.<sup>44</sup> A child who is very active in the first few years of life and has had, by the age of two or three, multiple bleeds into one particular joint, may develop a 'target' joint. In that event, the child is much more likely than other children with haemophilia to get bleeds later on in life.<sup>45</sup> Lifestyle can also affect older patients. Playing football as goal keeper in a Sunday league, for example, can expose that individual to a greater risk of bleeding than other mildly affected haemophilia patients with the same factor levels.<sup>46</sup>

**2.30** When patients suffer recurrent untreated haemarthroses (bleeding within a joint), the joints are rapidly destroyed by secondary osteoarthritis.<sup>47</sup> When this occurs in knee joints walking becomes slow and painful.

**2.31** On the other hand, it is a mystery why some severely affected patients do not bleed more often. Dr Winter said:

We don't know why ... [severely affected haemophilia patients] don't bleed more often. They have no Factor VIII, so why do they only bleed naturally 30- to 40-ish times per year? We have evidence they are more likely to bleed when they are infected. That's probably because the infection affects the way their platelets work, which is the other part of the clotting mechanism apart from clotting factors.

<sup>41</sup> Dr Winter – Day 15, pages 61–62

<sup>42</sup> Ibid page 62

<sup>43</sup> Dr Colvin – Day 2, page 81

<sup>44</sup> Ibid page 87; Dr Winter – Day 15, page 62

<sup>45</sup> Dr Winter – Day 15, pages 62–63

<sup>46</sup> Ibid page 65. The example was not hypothetical.

<sup>47</sup> Professor Ludlam explained the difference between osteoarthritis and osteoarthritis (Day 18, page 28). He advised that most of the chronic changes in bones are osteoarthritis whereas osteoarthritis refers more to an inflammatory component.

We have evidence that bleeding is much more common in a joint when the joint has been previously damaged. I think that ... micro-bleeding is probably happening the whole time in joints and muscles, which is the site of main pathology in haemophilia.

But the patient ... can't actually work out whether the minor ache in his knee is due to his arthritis or is it due to a new bleed. Some of these episodes of bleeding will reach a greater threshold, where the bleeding is obviously very significant, but ... our suspicion is that a lot of episodes of bleeding are subclinical and attributed by the patient to the inflammation that he experiences day to day because of all the previous joint damage. Certainly if you go to an operation on somebody's joint ... you can see that the lining of the joint looks like mushroom risotto, for want of a better word, and that it is very bloody.

So one would expect that these joints have been damaged by bleeding early in life ... [T]he synovium, the lining of the joint, becomes much more friable and, like fronds of sea weed, waves in the cavity of the joint and, naturally enough, that can be a focus for very, very tiny episodes of bleeding.

Obviously, if the patient then has trauma – about half of our patients would come in and say, 'I have a bleed. I know why. I banged my elbow coming down the stairs.' About half of them would say, 'I woke up this morning, I have a bleed and I don't know why.' So these things are by no means as well understood as you might think.<sup>48</sup>

**2.32** The bleeding patterns in haemophilia are complex because they are variable. Although it is reported that patients get around of 30-40 bleeds a year, an absolute characteristic is that whole weeks might pass with no problems and there might then be a run of several bleeds over a few weeks. A particular precipitating factor, especially in children, is a concurrent infection, such as an ear infection, with bleeding more likely to happen in that situation.<sup>49</sup>

**2.33** In the case of mild haemophilia, factor levels may vary from time to time. Factor VIII is an acute phase protein, a protein the levels of which fluctuate, even in healthy patients, in response to tissue injury. This variability is seen more often in mildly affected patients, depending both on how the test is done and on the general health of the patient. For example, patients who have developed arthritis in older age, and therefore have ongoing inflammation, may show an increase in background Factor VIII from 20 to 30 iu/dl. Classification might change permanently if a patient with mild haemophilia develops an inhibitor to factor therapy: that would convert the individual into a more severely affected patient.<sup>50</sup> Illness of any kind might cause a transient increase since inflammation or infection may increase the general activity of several acute phase proteins. A patient's normal Factor VIII level of 20 iu/dl might transiently go up to 30 if he gets pneumonia, for example. In addition, Factor VIII assays are not necessarily the easiest test to carry out and different laboratories testing the same sample might produce different results.<sup>51</sup> The figures for Factor VIII levels in any particular case can give an impression of precision which is not achieved in clinical practice.

---

<sup>48</sup> Dr Winter – Day 15, pages 66–67

<sup>49</sup> Dr Winter – Day 15, page 63

<sup>50</sup> Ibid, pages 63–64

<sup>51</sup> Ibid, page 59

**2.34** Fluctuation in factor level is less likely in people with severe haemophilia. In a significant percentage of patients there is the deletion of a gene responsible for Factor VIII production so that they cannot make any Factor VIII at all and their Factor VIII level will not increase as an acute phase protein because, even if they have an illness such as pneumonia, the liver cannot make any Factor VIII under any circumstances.<sup>52</sup>

**2.35** Dr Colvin explained some common situations:

Children with severe haemophilia usually present, in the first 18 months of life, particularly at the time when they begin to get up and run around or crawl around and bump into things. So the little child with severe haemophilia gets bruises on the shins and may develop haemarthrosis, particularly in the knees and ankles, or when they are trying to put toy soldiers into their mouths, they may cut the mouth and get bleeding from the mouth.

So many children with severe haemophilia who don't have a family history may find – or their parents may find – that they are accused of non-accidental injury, which of course is extremely upsetting for someone who later proves to have a significant blood disorder. But when you are dealing with children with mild or moderate haemophilia ... spontaneous bleeding or bleeding after minor injury is not quite so common, so that you may need quite a significant injury in order to cause bleeding. For example a dental extraction, a classical injury which would cause trouble, or if there is a more important injury, where ... there is a twisted ankle or a twisted knee that may lead to bleeding or at the time of a major contusion like falling off your bicycle or having an operation.

So the person with mild to moderate haemophilia may remain undiagnosed for quite a long time, and being diagnosed at the age of 5 or 6 or 7 years is pretty routine and I have seen patients being diagnosed with mild haemophilia in their 60s and 70s. So it just depends on the level of trauma to which you are subjected. But ... to be diagnosed with haemophilia perhaps after dental extraction at the age of 7 is absolutely typical of the condition.<sup>53</sup>

**2.36** It was suggested to Dr Colvin that people with severe haemophilia may experience bleeding without a trigger. He said:

That's true, although the majority of bleeding in severe haemophilia takes place into the joints and muscles, which are the moving parts. However, it is the case that people with haemophilia, particularly severe haemophilia, may have spontaneous [bleeding] – intracranial haemorrhage is the best example – where there is clearly no discernible trigger. Maybe somebody might have bumped their head, but there is no doubt that some people with haemophilia, particularly severe haemophilia, have truly spontaneous bleeding. Of course, it is still possible that there might have been some minor defect in the circulation within the brain that pre-disposes to this spontaneous bleeding. So the word 'spontaneous' is certainly valid in everyday speech; whether it is completely valid at a scientific level is less clear.<sup>54</sup>

---

<sup>52</sup> Ibid, page 60

<sup>53</sup> Dr Colvin – Day 2, pages 78–79

<sup>54</sup> Ibid, pages 83–84

**2.37** Dr Winter's views on the prevalence of sub-clinical bleeding have been noted at paragraph 2.33. Professor Christopher Ludlam, Director of the Edinburgh Haemophilia Centre, commented on bleeding into the brain in particular:

It is likely that ... we all have a small amount of bleeding in our brains from time to time. We all have good – or most of us have good clotting systems and it stops very quickly and heals up. The problem in haemophilia is that once bleeding starts, it takes a long time to stop. You do not necessarily get a greater flow of blood but it just goes on and on and on and on, and if that happens in the brain, then it often has catastrophic consequences.<sup>55</sup>

**2.38** Mild haemophilia does not imply mild bleeding. Once a person with mild or moderate haemophilia begins to bleed after an event such as a tonsillectomy, he will go on bleeding until something is done. A tonsillectomy could be life threatening because a large amount of material is removed from the throat and the airway is critical: death from bleeding could very easily take place.<sup>56</sup>

**2.39** Because the severity of haemophilia in an individual may not correlate with the frequency of treatment with blood products, it is not possible definitively to associate the severity of haemophilia with the risk of infection from blood products. Perhaps the most one can say is that there is a broad relationship between risk from replacement therapy and the individual's history of bleeding that required replacement therapy.

### *Impact of haemophilia*

**2.40** The balance of risk and benefit in the use of blood, blood components and blood products in general medical and surgical practice may often be relatively uncomplicated. In extreme cases, without a transfusion the patient may die in the course of treatment for the condition requiring medical intervention. Lifelong treatment for an incurable condition, which haemophilia generally is (short of liver transplantation), raises more complex questions. The forms of therapy available for managing the condition change over time, and with those changes come changes in the benefits and in the risks associated with them. Choice of therapeutic materials may become an issue, and any risk/benefit analysis is inevitably complicated by that. The patient's response to therapy may also change. Throughout, however, there is one factor in the balance of risk and benefit that is relatively stable: the risk of progressive illness and death that is inherent in blood coagulation disorders. It is clear that those risks, reflected in morbidity and mortality rates, influenced patients, the Haemophilia Society and haemophilia clinicians. It is important to take note of these risks as the history of treatment and increasing knowledge of risk developed.

**2.41** The extent to which patients' lives and life expectancy were compromised before clotting factor concentrates became available was noted in the Preliminary Report and reference was made to reported studies.<sup>57</sup> According to the studies referenced, life expectancy was increased by the use of factor replacement therapy until a position was reached, in 1977–79, when median life expectancy in moderately affected haemophilia patients was estimated to exceed by several years that of the general male population. Median life expectancy for severely affected haemophiliacs (defined as <2% Factor VIII

---

<sup>55</sup> Professor Ludlum – Day 18, pages 22–23

<sup>56</sup> Dr Colvin – Day 2, page 88

<sup>57</sup> Preliminary Report, paragraphs 3.46–3.49, noting that the Birch Report was a study from Illinois.

at this stage) remained a little below the median for the general population. The oral evidence led at the Inquiry was more direct and emphasised the adverse consequences for patients of bleeding episodes over time.

**2.42** In his written submission to the Archer Inquiry,<sup>58</sup> Dr Winter wrote about life for the haemophilia patient before effective treatment was available:

Without treatment we know that life expectancy is very limited. The Birch report in the 1930s disclosed that only 20% of patients with severe Haemophilia could expect to live beyond twenty years. A Finnish study in 1960 showed that the average life expectancy for patients with severe Haemophilia was twenty five years. The commonest cause of death was internal bleeding, particularly into the brain or gastro intestinal tract. Although Haemophilia appears to have been around for a very long time, no treatment was available until the early 1960s because factor VIII circulates in the blood in only tiny amounts and no way had been found of concentrating factor VIII from blood.<sup>59</sup>

**2.43** Dr Winter commented in oral evidence on the natural history of haemophilia:

I think it may be relevant to say that if you ... want evidence of what happens when somebody with severe haemophilia doesn't get treated, you don't only need to look back to these retrospective studies, which were a long time ago and not many of them, you can go to one of the developing countries because the cost of concentrate is so significant, there are many developing countries where, as in Pakistan, they have got very nice hospitals, experienced doctors, good nurses, they are a nuclear power, but they have no concentrate. In the centre in Islamabad, where we visited twice, there are upward of 250 children with severe haemophilia, of which one of them lived beyond the age of 18.

So that remains the natural history of haemophilia. Without treatment, as happened to members of the Royal Family, the likely thing by far is that you will have some life-ending event of serious and spontaneous internal haemorrhage before the age of 20 or so years. That is the natural history of severe haemophilia.

....

You can look at the old footage of the Tsarevich being carried round Moscow at the age of 8 and he is completely crippled and can't walk, and in Pakistan hardly any of the children we were doing clinics with, hardly any of them – certainly none of them had normal joints and most of them were bedbound.<sup>60</sup>

**2.44** Untreated, haemophilia has always been, and remains, a serious, debilitating and potentially fatal disease. It is clearly this factor that has, throughout the reference period, driven the search for therapeutic materials and methods intended to reduce exposure to risk of bleeding or to treat the patient for bleeds when they occur, which has for much of that time involved the risk of transmission of viral infections.

<sup>58</sup> The Archer Inquiry was an independent, non-statutory Inquiry on 'NHS Supplied Contaminated Blood and Blood Products' chaired by Lord Archer of Sandwell which reported in 2009.

<sup>59</sup> Dr Winter's submission to the Archer Inquiry [PEN.015.0283]

<sup>60</sup> Day 15, pages 56–57

### *Treatment of haemophilia and risks*

**2.45** By the commencement of the reference period, the main preparations used in the treatment of haemophilia were early forms of factor concentrates and cryoprecipitate. The history of production and use of these materials in Scotland is discussed in Chapter 20, *Haemophilia Therapy – The Period up to the Early 1980s* and Chapter 21, *Haemophilia Therapy – Use of Blood Products*.

### **Cryoprecipitate**

**2.46** Cryoprecipitate was the first effective treatment for bleeding that was readily available throughout Scotland.<sup>61</sup> It was prepared, mainly at RTCs in the opening years of the reference period, from individual blood donations.<sup>62</sup> In use, it was a high-volume product. Typically, doses used in treatment required a number of units to be administered at the same time. In Glasgow and the West of Scotland, an ‘empirical daily dosage scheme’ was adopted from the mid-1960s: 10 packs were used for minor bleeding episodes and 20 packs for major episodes, with further infusions as required. A patient treated at the Glasgow Centre in accordance with the empirical dosage scheme might have 20 bleeds in the course of a year, each requiring treatment for four days with 20 packs of cryoprecipitate per day. In the course of the year the patient would have been exposed to 1600 units (20 x 4 x 20) derived from up to 1600 donors.<sup>63</sup>

**2.47** At the levels of usage implied, for patients requiring frequent treatment, cryoprecipitate exposed the recipient to a large number of donors. It was soon recognised that cryoprecipitate might be associated with transmission of virus infection. In 1966, Vincent del Duca and R. Bennet Eppes reported the transmission of hepatitis following use of cryoprecipitate.<sup>64</sup> Two Glasgow patients were reported in 1969 to have had jaundice after infusion.<sup>65</sup> They also had received blood and FFP and the report was tentative in respect of any relationship between infusion and infection. Dr Judith Pool<sup>66</sup> responded to del Duca’s 1966 report of transmission:

We are not aware of this complication after the administration of more than 3000 cryoprecipitates in our own institution, but know of no reason why such preparations should be any more free of transmissible hepatitis than other single donor units given in large numbers.<sup>67</sup>

**2.48** Dr Pool’s response acknowledged the risk inherent in multiple treatments with cryoprecipitate. While each unit of cryoprecipitate had a single donor origin, the accumulation of units for any one treatment and of repeated treatments over time exposed the recipient to increasing risk. At the level of use suggested by the empirical dosage scheme in Glasgow and the West of Scotland, the risk of transmission in the course of a year was as great as would have arisen from use of the large pool concentrates eventually produced in Edinburgh.

<sup>61</sup> Cryoprecipitate is the solid residue which remains after the thawing of frozen plasma. It contains most of the Factor VIII from FFP.

<sup>62</sup> Paragraph 3.27 of the Preliminary Report is inaccurate in stating that units of the product were prepared from many litres of plasma.

<sup>63</sup> As noted in paragraph 2.64 below, Dr Winter said that some patients had treatment 30-50 times a year or even more. Evidently, such patients would have been exposed to yet more units (and donors) than in the example given above.

<sup>64</sup> Del Duca and Eppes, ‘Hepatitis Transmitted by Antihæmophilic Globulin’ *New England Journal of Medicine*, 1966; 275:965 [PEN.018.1455]

<sup>65</sup> Forbes *et al*, ‘Cryoprecipitate Therapy in Haemophilia’ *Scottish Medical Journal* 1969, 1: 1 – 9 [LIT.001.4018]

<sup>66</sup> Dr Pool was a physiologist at Stanford University who, in 1964, discovered cryoprecipitate.

<sup>67</sup> Judith Pool, Letter to the Editor in Response to Del Duca and Eppes (q.v.) *New England Journal of Medicine*, 1966; 275: 966 at 1456 [PEN.018.1455] at 1456

**2.49** The administration of cryoprecipitate involved some problems. It was very laborious to prepare, taking two people up to an hour to prepare a dose from about 20 frozen bags, which had to be removed from deep freeze, thawed in a water bath and then reconstituted. Given the nature of the production processes involved, the Factor VIII activity in each bag was not measured and was not known, and clinicians could not scientifically calculate the dose required for the patient. It was difficult to inject and particularly difficult to administer to children.<sup>68</sup>

**2.50** Cryoprecipitate could also have quite significant side effects.<sup>69</sup> Some patients who had multiple previous transfusions, which included most haemophilia patients receiving treatment, might react against protein impurities in the cryoprecipitate and that could make the administration of the cryoprecipitate quite an unpleasant experience for the patient. Over the period of an hour the patient might shake and shiver, run a fever, have muscle aches and feel generally unwell.<sup>70</sup>

**2.51** The difficulties in administering cryoprecipitate and the practical problems sometimes associated with access to treatment in hospital out-patient departments are discussed in Chapter 21, *Haemophilia Therapy – Use of Blood Products*. Dr Winter emphasised that it was a very harrowing experience for the patient. He had never, in all his years of haemophilia practice, heard a patient say, 'I went to casualty with a bleed and everything went well'. He said that never happened. Not only was cryoprecipitate not a very good medical treatment for the patients, having to go to hospital to have that treatment was 'a dreadful experience'.<sup>71</sup>

**2.52** The incentive to use concentrates when they became readily available was clear. The introduction of concentrates, and increase in their supply in the mid-1970s, heralded a major revolution in haemophilia care. Before then, schooling in particular had been so variable an experience for children with haemophilia that there was a dedicated boarding school in Hampshire, the Lord Mayor Treloar School, for patients with haemophilia. When concentrates became available, boarding provision was no longer required.<sup>72</sup> Concentrates were much easier to use than cryoprecipitate and in particular, unlike cryoprecipitate, they did not need to be stored deep-frozen.

### Factor concentrates

**2.53** Early Factor VIII concentrate, known as Cohn Fraction 1, was prepared in Edinburgh from the 1950s, using plasma from about a dozen donations. Cohn Fraction 1 was reported to be associated with the transmission of hepatitis in the 1960s.<sup>73</sup>

**2.54** As far as the patient was concerned, risk was a function of the number of units infused, in the case of cryoprecipitate and early small-pool concentrates. In the course of the reference period, progressive technological development increased the volume of plasma used to produce a single batch of factor concentrates to a point where many thousands of donations were pooled together by some manufacturers. Before effective virucidal treatment of blood products became available, that inevitably increased the number of recipients exposed to risk from a single batch of product. However, there was

<sup>68</sup> See Professor Ludlam's descriptions of use of cryoprecipitate – Day 18, pages 32–38

<sup>69</sup> Dr Winter – Day 15, Page 79

<sup>70</sup> Ibid Pages 81–82

<sup>71</sup> Ibid Pages 79–81

<sup>72</sup> Ibid Page 73

<sup>73</sup> Marder and Shulman, 'Major Surgery in Classic Hemophilia Using Fraction I' *American Journal of Medicine*, 1966; 41:56-75 [PEN.018.1432]

an incentive to use the newer products in light of the advances they brought in clinical management of the patient.

**2.55** In the case of later concentrates, risk was primarily a function of the number of units used in their production. At about the beginning of the reference period, batches of fractionated product produced at the Royal Infirmary of Edinburgh Royal Infirmary had already involved hundreds of donation units and, with the move to Liberton, 1000 units was the initial batch quantity. Very few infusions of concentrate were required to raise the risk of virus transmission to levels approaching 100%.

### *Changes in patient management*

**2.56** Factor concentrates opened the door to home therapy as clinicians could issue concentrate that was small in volume and could be kept in a domestic refrigerator. The concept of comprehensive care evolved. Usually from the age of about three, depending on the state of the child's veins and the competence of the parents, the family would be taught how to inject and the patient would go on home therapy for the rest of his life. The patient would then attend clinic every two to three months, depending on the severity of the disorder, for a comprehensive clinical review.<sup>74</sup> The breakthrough brought a 'golden interval' that lasted from about 1973 until the years of viral contamination problems began some five or six years later. Dr Winter said that haemophilia patients were having better attendance rates at school, getting decent jobs and receiving early treatment at home for their bleeds. There were fewer joint problems.<sup>75</sup>

**2.57** In its initial phase, home therapy, like earlier hospital treatment, was used in response to need when the patient had or anticipated a bleed. Some adult haemophilia patients reported an early and brief phase of a few minutes when they had an 'aura' that indicated that not all was well. That would be followed very soon by obvious clinical signs of the bleed, wherever in the body it might be. For joint bleeding, the major clinical indicator would be pain or swelling. Patients were taught that, because the joint was very hot due to the blood in it, they should rub the back of the hand over the affected joint, such as the knee, and compare the good joint with the bad. If the bad knee was a lot hotter, that was a very good sign of an acute episode of bleeding. If the patient were a child, he might be in distress, in particular if the parent passively tried to move the joint, by straightening the knee and the ankle. The child would resist because it was painful, as well as it being hot. In day-to-day home life it was usually obvious that the child did have a bleed, if it was into a joint or a muscle.<sup>76</sup>

**2.58** For many years cerebral bleeding was the leading cause of death in haemophilia patients. It has not been eliminated even today but its incidence is very much lower than it was 30 years ago. Identifying major risks was a significant focus for teaching families before a patient went on home therapy. Instruction included the identification of times when it was of the utmost importance that the centre should be contacted immediately, day or night, for assistance. Those included cases in which a child had a significant head injury, lost consciousness or started to vomit after a head injury. Another major area of concern was bleeding into the mouth. If any of these things were to happen, patients and parents were taught to get in touch right away because the centre would wish to administer clotting factor concentrate very quickly and to assess the child clinically.<sup>77</sup>

---

<sup>74</sup> Dr Winter – Day 15, Pages 72–73

<sup>75</sup> Ibid Page 73

<sup>76</sup> Ibid pages 75–76

<sup>77</sup> Ibid pages 76–77

**2.59** In theory, home treatment in response to a bleed might not have been expected to increase the risk of viral infection: the availability of home treatment did not increase the risk of a bleed. Patients did not, however, always seek treatment at hospital before the advent of home therapy. Having regard to Dr Winter's evidence, there was an incentive to put up with the pain and inconvenience of a minor bleed rather than go to hospital. It would be reasonable to infer that there would be an increase in use of concentrate because of the convenience afforded by home treatment and, therefore, an increase in viral infection risk overall.

**2.60** The next stage in the development of practice was the introduction of prophylaxis in the 1980s. A practice pioneered by Swedish physicians, it followed the observation that, if a child with severe haemophilia was given Factor VIII or Factor IX regularly (three times a week in this study), then, although their factor levels were not normalised, a baseline zero per cent level of Factor VIII would be changed into a baseline of five per cent. Although the patient would still bleed on even minor trauma, he would not bleed spontaneously. Prophylaxis became widespread practice in Europe.<sup>78</sup>

**2.61** Superficially, it might seem reasonable to infer that increasing use of factor concentrates, with home treatment and with prophylaxis, was accompanied by increasing risk of viral infection. However, there was evidence, referred to in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, that early treatment helped prevent bleeds from developing and that had a beneficial effect on total consumption of factor concentrates.

**2.62** Commercial concentrate production, on which English haemophilia practice in particular was heavily dependent, had by the mid-1970s come to involve the processing of very large plasma pools. Before effective virus inactivation, the risk inherent in the product itself had increased. Dr Winter said:

That was my understanding, that by the time concentrate production was well underway by the mid 1970s, the pool size would be at least 20,000 and sometimes higher.

....

The mathematics is actually quite straightforward. There are studies showing that the incidence of the virus that we now know as Hepatitis C in US donor plasma in the 1970s was of the order of 1 per cent. So if you were giving somebody with haemophilia a treatment that came from 20,000 donors, and one in 100 of them had Hepatitis C, each time the patient had a treatment they were getting a couple of hundred, at least, different Hepatitis C infections, and of course this treatment was being given to them maybe 30 to 50 times a year, or even more often than that.

So our understanding, as haemophilia doctors, is that it was absolutely inevitable that if you had Factor VIII concentrate in the 1970s, particularly from US donor plasma, it was absolutely inevitable that you were getting a number of different Hepatitis C infections, and clinically quite an interesting observation that has been made is Hepatitis C comes in different genotypes, six different genotypes – I say quite often, there have been quite a few experiences in my centre and in a number of other centres that we have treated a patient with a

---

<sup>78</sup> Ibid pages 73–74

known genotype, say genotype number 1, and we have cleared that genotype and retested him to be then told by the viral laboratory we have now found another genotype. So our understanding based on this mathematics is that these patients were multiply infected with Hepatitis C, as we now call it.<sup>79</sup>

**2.64** There was less extensive use of imported concentrate in Scotland generally. Imported, commercially-produced Factor VIII was used, however, especially in Edinburgh and Glasgow, from time to time, and specialised imported products were used more widely.<sup>80</sup> The use of domestic Scottish products was believed to carry less risk because the pool size was smaller and the prevalence of infection in the donor population was thought to be lower than in the USA. The differences were not sufficient to eliminate risk in Scotland, however, and in time it came to be understood that the general position remained the same as elsewhere: the move to concentrates increased the risk of transmission of viral infection. Regular prophylactic rather than reactive treatment may have increased exposure and risk further, whether Scottish or imported products were used, at least as far as Hepatitis C was concerned.

**2.65** By the mid-1970s, many UK patients with haemophilia had liver function blood test results which, with the benefit of hindsight, were suggestive of a hepatitis-like pattern. The patients were, by and large, very well. It was possible to demonstrate that maybe 5%, perhaps slightly higher than that, had circulating levels of Hepatitis B; a small number could be demonstrated to have had Hepatitis A, so-called infectious hepatitis; and about 20% could be shown to have antibodies against Hepatitis B (and had therefore been exposed to Hepatitis B). However, for the majority of the other patients who had a hepatitis-like picture on their liver function blood tests, all the standard Hepatitis A and Hepatitis B markers were negative. Most were infected with 'non-A, non-B Hepatitis' as a result of the use of factor concentrates, which only unusually gave clinical symptoms. That was not understood at the time.<sup>81</sup>

### *Risks of transmission: HCV*

**2.66** The risks of transmission of HCV by administration of therapy for coagulation disorders in Scotland were largely eliminated by the introduction for clinical use of effective virus inactivated concentrates (Factor IX in October 1985 and Factor VIII in April 1987).<sup>82</sup> Until those dates, all patients in treatment were exposed to risk of infection.

### *Risks of transmission: HIV*

**2.67** As with HCV, the risks of transmission of HIV were substantially eliminated by the introduction of effective virus inactivation of factor concentrates (December 1984/January 1985).<sup>83</sup> Patients were exposed to risk of infection throughout the early 1980s, though that did not become apparent until 1984. It is now clear from the phylogenetic analysis of retained samples that very few HIV-infected individuals donated blood during the few critical years before effective viral inactivation was introduced.<sup>84</sup>

<sup>83</sup> See Chapter 24, *Viral Inactivation of Blood Products for Haemophilia Therapy*, paragraphs 24.8–24.9 and Chapter 3, *Statistics*, paragraph 3.43

<sup>84</sup> The Edinburgh Cohort of eighteen patients who were found to have acquired HIV infection in 1984 were associated with two (possibly three) donors. See Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paragraphs 10.121–10.122. Phylogenetic analysis, which enables the definition of genetic relationship among samples from several sources, was vital to this discovery and is discussed in that chapter.

### Other people exposed to risk

**2.68** As noted in the Preliminary Report, other people were exposed to the risk of transmission of viral infection in a National Health Service context, specifically clinical and laboratory staff and other hospital workers and researchers.<sup>85</sup> They were exposed to all of the consequences of infection to which those presenting as patients were exposed. These people became patients as a result of participation in treatment and other operations.

**2.69** In Edinburgh, the risk was illustrated in the transmission of 'infectious jaundice' (in this case Hepatitis B) in the Medical Renal Unit at the Royal Infirmary and the Nuffield Transplantation Surgical Unit at the Western General Hospital between June 1969 and May 1970. There had been two previous cases but, in this short period, 18 cases of infection occurred in dialysis patients and six in people who had had contact with dialysis patients. Four of the contacts were members of staff and two were relatives of patients. In the same period four of the 18 patients had died. One member of staff had died and an additional member of staff, a clerk in the haematology department at the Western General Hospital, had also died.<sup>86</sup> Though not within the Terms of Reference, these examples show that the classes at risk from time to time were wider than those who came into NHS care as patients in the first instance.

### Summary

**2.70** Successive developments in clinical practice reduced risks to patients, although, on the whole, they did not change patients' needs for treatment. As with all innovations aimed at patient safety, they removed or reduced the risk, or some of the risk, that was known to be inherent in previous practice. Other risks remained. All red cell therapy, for example, continued to carry a risk of transmission of HCV, until routine screening of blood for antibodies to Hepatitis C was introduced in the UK on 1 September 1991.

**2.71** Throughout the reference period there was significant use of human blood and blood components, FFP and cryoprecipitate in surgical and medical practice. Patients receiving transfusions have been among those exposed to the risk of transmission of virus infection. Estimates of the numbers of patients who may have been infected are discussed in Chapter 3, *Statistics*, and a summary has been noted in paragraph 2.1 above. Taken together, transfusion patients represent the largest cohort of NHS patients relevant for the purposes of this Report.

## CHAPTER 3

### STATISTICS

#### Introduction

#### 3.1 Term of Reference 4 required the Inquiry:

To investigate the systems for recording and monitoring the numbers of NHS patients in Scotland treated with blood and blood products, with particular reference to the numbers exposed to risk of infection with the Hepatitis C virus and HIV and the numbers contracting either or both such infections as a consequence of such treatment.

**3.2** The National Health Service (NHS) patients who were treated with or received blood and blood products and were put at risk of infection with both HIV and the Hepatitis C virus (HCV), or HCV alone have been described in Chapter 2, *Patients at Risk* paragraph 2.1. This chapter attempts to estimate the numbers of patients infected with one or other or both viruses. For the purposes of this chapter, the patients are divided into four groups:

- i. Patients with bleeding disorders who were infected with HCV as a result of treatment with blood products.
- ii. Patients who were infected with HCV as a result of blood transfusion.
- iii. Patients with bleeding disorders who were infected with HIV as a result of treatment with blood products.
- iv. Patients who were infected with HIV as a result of blood transfusion.

Surgical and medical patients transfused with blood and blood components are the largest group of NHS patients exposed to infection by HCV.

**3.3** Within the group of patients with blood coagulation disorders, some sub-groups, including female carriers of the disorders now recorded in the statistical registers, have become numerically significant in the past decade. Very few of these were known, and fewer still received blood products in the 1970s and 1980s. The numbers of those patients infected or potentially infected with HCV or HIV are very small indeed. They do not affect the overall picture and are not discussed separately in this chapter.<sup>1</sup>

**3.4** The search for reliable data for the numbers of patients treated by the NHS in Scotland with blood, blood components or blood products and thereby exposed to risks of transmission of HCV and HIV, and of the numbers who were infected, has proved for the most part to be extremely difficult. Contemporary records, whether of patients exposed to risk or of the incidence of infection, were either not maintained at all, or have become over time incomplete and unreliable. For much of the period it would not have been possible to maintain contemporaneous records of transmission of infection, given the dates when the viruses responsible for the diseases were first identified. This is particularly the case in respect of patients infected with HCV as a result of transfusion. The picture is clearer in the case of HIV infection where reports of infection arose over a

---

<sup>1</sup> The witness 'Christine' is a carrier of Haemophilia A and contracted HCV from a transfusion of Factor VIII prior to surgery in 1981. See Chapter 6, *An Examination of the Effects of Infection with Hepatitis C on the Patients and their Families, Including Treatment*.

relatively short and well-defined period of time. These records were recent and appear to have been reasonably reliable. Investigation of transmission was possible in many such cases.

**3.5** However, even in the case of HIV, reports of the numbers of patients infected with the virus, or suffering from AIDS, in the UK generally and Scotland in particular have not always been consistent or comprehensive. Further, it became apparent during the Inquiry's investigations that information has not been disseminated equally among professional groups directly involved in patient care, other related professional groups, patient groups and the general public, with the result that there are inconsistencies among the sources of information that have been difficult, or even impossible, to resolve.

**3.6** As a result of work carried out after the oral hearings, by the Scottish Haemophilia Directors and Dr Charles Hay and colleagues at the National Haemophilia Database, it is now possible to be confident of the number of patients with blood disorders who acquired HIV infection from therapy administered in Scotland. It has not been possible without some qualification to arrive at precise figures for the numbers of patients actually infected in any of the other three groups. Recorded, hard data contribute to the overall picture, but there are no comprehensive NHS records of unquestionable accuracy for either disease in any category of patients, extending over the whole of the period under review.

**3.7** A short answer to Term of Reference 4 would be:

- In the case of each infection there was a period when the agent of transmission was not identified, and no diagnostic test for infection was available, so an effective recording of comprehensive data would therefore have been impossible.
- During the period in question there were no satisfactory regulatory or other central administrative systems for recording and monitoring the numbers of NHS patients in Scotland treated with blood and blood products, or the numbers exposed to the risk of infection with HCV or HIV, or the numbers contracting either or both such infections as a consequence of such treatment.
- Such provision as was devised for reporting and recording relevant data was not enforced and was ineffective.

**3.8** However, notwithstanding the lack of systematic recording and monitoring of patients, it was recognised by the Inquiry that it might be possible for a retrospective analysis to be carried out, either by extraction and analysis of the material found, or using this basic data for statistical analysis and projection. The investigation has therefore been extended to include more complex study in order to determine whether relevant information can be deduced from available data using statistical modelling techniques.

### **Systems for reporting and recording infection**

**3.9** Infection of the liver with hepatotropic viruses has generally been seen as an issue only since the Second World War, partly because blood transfusion (in the broadest sense) has been practised widely only since then. It is only relatively recently, since the 1960s, that the impact on the human population of 'viral hepatitis' has been perceived at all.<sup>2</sup> From 1932,

---

<sup>2</sup> Professor Zuckerman pressed for notification of hepatitis in 1966 as essential for the measurement of the scale of post transfusion hepatitis in the UK: 'Correspondence – Blood Transfusion and Infectious Hepatitis', *British Medical Journal*, 5 November 1966: 1136 [LIT.001.0247]

there was a requirement to notify cases of 'infective jaundice' but 'infective jaundice' was defined exclusively as 'spirochaetosis ictero-haemorrhagica', indicating an 'icteric' or symptomatic condition.<sup>3</sup> In 1968, that limited definition was removed, and the notifiable disease became 'infective jaundice', without further definition.<sup>4</sup> One aim of this change was to assist Medical Officers of Health to obtain more precise information about the prevalence of hepatitis and the circumstances in which it was spread.<sup>5</sup> Growing awareness of the prevalence of hepatitis (in the broadest sense of disease causing inflammation of the liver) in the UK, led to provision for notification of cases of 'viral hepatitis', which became reportable as an infectious disease under the Public Health (Infectious Diseases) (Scotland) Regulations 1975, which came into force on 2 April 1975.

**3.10** Retrospective studies from America and modelling studies from France, in addition to data and studies from the health protection agencies, suggest that, in Western countries generally and in Scotland in particular, the rate of growth of NANB Hepatitis/HCV infection accelerated through the 1970s and 1980s, largely related to intravenous drug use.<sup>6</sup> The rate of growth slowed thereafter, but the numbers infected continue to grow, and are expected to increase well beyond 2020.<sup>7</sup> Until the second half of the 1980s NANB Hepatitis infection was generally thought not to be a potentially serious condition.<sup>8</sup> So far as present purposes are concerned, this goes some way to explaining the lack of data on the incidence and prevalence of the disease, both generally and among haemophilia and other NHS patients. Furthermore, until discovery of the HCV virus in 1988 and subsequent epidemiological studies in the 1990s, NANB Hepatitis was thought probably to be due to more than one agent, and could not be identified by any serological test available. The background facts were not conducive to the development and implementation of an effective reporting strategy.

### *The Public Health (Infectious Diseases) (Scotland) Regulations 1975*

**3.11** Under the 1975 regulations a medical practitioner, on becoming aware that a patient was suffering from a notifiable disease, had a legal obligation to inform the chief administrative medical officer for the area health board 'forthwith' by means of a prescribed certificate.<sup>9</sup> The regulations required only bare details to be given and did not address the possible or likely means by which the disease had been contracted.<sup>10</sup> The chief administrative medical officer for each health board had an obligation, at the end of each week or as soon as practicable thereafter, to send to the Common Services Agency for the Scottish Health Service (the CSA) a return of the number of cases of each notifiable disease intimated to them during that week.<sup>11</sup> In addition, they had an obligation to report immediately to the Chief Medical Officer any serious outbreak of any infectious disease which, to their knowledge, had occurred in their area.<sup>12</sup>

<sup>10</sup> *Ibid* Schedule 2

<sup>11</sup> *Ibid* Regulation 4

<sup>12</sup> *Ibid* Regulation 7

**3.12** The system was not effective. The regulations, which were unfortunately introduced just before the several distinct forms of viral hepatitis and their clinical manifestations began to be understood, did not promote epidemiological understanding of hepatitis. The existence of an NANB Hepatitis virus or viruses (in time, principally Hepatitis C) had only recently been postulated (in 1974) when the regulations came into force in 1975. Professor David Goldberg's group at Health Protection Scotland (HPS), (which collects and analyses statistical and epidemiological data relating to blood-borne viruses, sexually-transmitted infections and other diseases and infections), and its predecessor the Scottish Centre for Infection and Environmental Health (SCIEH), concluded that such data as were returned and registered were not reliable.<sup>13</sup> The reports required of medical practitioners did not contain adequate information on the prevalence of infection.<sup>14</sup> Professor Goldberg explained further that, following the 1991 introduction of reliable testing and screening for HCV, it soon became clear that the numbers reported by clinicians bore no relationship to the actual data HPS recovered from laboratories testing samples for evidence of infection. They found that data recorded by virology laboratories were over 90% complete and accurate, undermining the reliability of the different and inconsistent data held on the register. Use of the data reported under the regulations would have hindered HPS in developing its understanding of the epidemiology of HCV infection.<sup>15</sup>

**3.13** The regulations could never have been effective in securing full reporting of the incidence of viral hepatitis. There were several problems with the regulatory regime. 'Viral hepatitis' is not a specific disease. It can be caused by a number of hepatitis viruses.<sup>16</sup> Until well into the reference period not enough was known about the forms of viral hepatitis to enable effective reporting requirements to be developed and enforced. Professor Goldberg said that, in reality, clinicians rarely reported the clinical entity, viral hepatitis, to health boards.<sup>17</sup> Interpretation of the regulations as amended from time to time appears to have given rise to difficulties.

**3.14** NANB Hepatitis/Hepatitis C infection could not be diagnosed without a definitive test for the virus or its antibody. Until 1989–90 there was no diagnostic blood test available generally, to demonstrate prior exposure to HCV. In the UK routine testing was not introduced until September 1991. When the regulations came into force in 1988, overt clinical jaundice was thought to be characteristic of viral hepatitis.<sup>18</sup> In time it came to be recognised, however, that most patients who contracted NANB Hepatitis/HCV did not develop jaundice and that transmission of infection was largely a silent event which would not have alerted clinicians to the obligation to report.

**3.15** Nevertheless, viral hepatitis remained in the scheduled list of notifiable infectious diseases under the Public Health (Notification of Infectious Diseases) (Scotland) Regulations 1988.<sup>19</sup> These Regulations consolidated, with amendments, the 1975 Regulations relating to the notification and prevention of infectious disease.

<sup>13</sup> HPS have been responsible for retaining this information since 2007, having taken over this role from the Information Services Division (ISD)

## European law

**3.16** As regards blood products, Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community Code relating to medicinal products for human use, included an obligation on Member States to take all appropriate measures to 'encourage' doctors and other healthcare professionals to report to a competent authority suspected adverse reactions.<sup>20</sup> The Directive also obliged Member States to establish a pharmacovigilance system whereby those who were authorised to market a medicinal product were required to report to the competent authority all suspected serious adverse reactions to the product.<sup>21</sup> Directive 2001/83/EC did not apply to whole blood, plasma or blood cells.<sup>22</sup>

**3.17** As regards whole blood and blood components (ie red cells, white cells, platelets and plasma), Directive 2002/98/EC introduced an obligation on Member States to ensure that any serious adverse events or reactions relating to the quality or safety of blood or blood components were notified to a competent authority.<sup>23</sup> The Directive was implemented in the UK by the Blood Safety and Quality Regulations 2005,<sup>24</sup> which required 'blood establishments'<sup>25</sup> and hospital blood banks to notify the Secretary of State of any serious adverse events or reactions relating to the quality or safety of blood and blood components.<sup>26</sup>

**3.18** Before the Blood Safety and Quality Regulations 2005 came into force, there were no effective regulatory obligations on clinicians or others to report NANB Hepatitis/HCV or HIV infection from blood transfusion. The 2005 Regulations improved the regulatory regime, but came into force after the events that are relevant to this report.

**3.19** The 2005 Regulations reflected growing knowledge of the characteristics of transmissible diseases and of the difficulty of tracing infected patients who had received transfusions many years previously, when there may have been differing standards, for example, between peripheral hospital blood banks and transfusion centres. While transfusion centres had been inspected for many years by the Medicines Inspectorate, hospital blood banks had not. The regulations stipulated for the first time that hospital blood banks and transfusion centres should be brought fully within the Medicines and Healthcare Regulatory Authority (MHRA) framework, and the role of the MHRA was strengthened accordingly. The provisions recognised a gap in the traceability of previous donations and therefore of the patients who received them. Traceability, with a proper 'trail', became entrenched in the new regime and an obligation was placed on clinicians, blood banks and the transfusion service to report formally to the MHRA when there was a serious adverse event in transfusion, such as transmission of virus infection.<sup>27</sup>

## *Public Health etc. (Scotland) Act 2008*

### Hepatitis C

**3.20** Since 2005, and following public consultation, the Public Health etc. (Scotland) Act 2008 added further requirements, effective from 1 January 2010.<sup>28</sup> The Act involved significant reform and modernisation of the public health/health protection regime in Scotland. Testing laboratories are now required to report to health boards information about infection of individuals testing positive for hepatitis viruses.<sup>29</sup> For Hepatitis B and Hepatitis A, that is important because there is a vaccine available for these infections and close contacts can be identified and offered vaccination. In the case of Hepatitis C the public health importance of reporting is less clear. There was, and is, no vaccine available. For that reason the close contacts of individuals who were infected with Hepatitis C are generally not contacted.<sup>30</sup> However, there are now increasingly effective treatments available for HCV which may be offered to those found to be infected, which will generate demand for more effective tracing of people possibly infected.

**3.21** In the 2008 Act, Hepatitis A, B, C and E viruses are scheduled as 'notifiable organisms', and the generic term 'viral hepatitis' has been removed from the list of notifiable diseases.<sup>31</sup> The Act requires the director of a diagnostic laboratory which has identified a notifiable organism to notify, within 10 days, the health board in whose area the diagnostic laboratory is situated, as well as the CSA (presumably, in practice, Health Protection Scotland), of certain information.<sup>32</sup> As in the previous legislation, only bare details require to be notified and there is no duty to include the possible or likely means by which the organism was transmitted.<sup>33</sup> Fundamentally, notification depends on there being a listed organism identifiable by laboratory testing. Where diagnosis of disease depends on a laboratory test, linking surveillance of diseases to the laboratory testing process is likely to be a much more satisfactory procedure than that under the previous notifiable diseases regime. HCV infection is not a notifiable disease reportable by medical practitioners in terms of section 13 of the Act.

### HIV/AIDS

**3.22** HIV never became a reportable disease under the regulations at any stage.<sup>34</sup> The AIDS (Control) Act 1987 required each health board to make periodic reports to the Secretary of State of information including the numbers diagnosed with AIDS, the numbers with AIDS who had died and the numbers of positive HIV antibody test results. The reports by health boards did not involve identification of individual patients and would have been based on the board's internal statistical records.<sup>35</sup>

**3.23** In 2006 the Scottish Executive consulted on public health legislation in Scotland. The analysis of responses to that consultation confirmed strong support for the repeal of the AIDS (Control) Act<sup>36</sup> as well as a majority view in favour of including STIs (of which

<sup>28</sup> [http://www.legislation.gov.uk/asp/2008/5/pdfs/asp\\_200885\\_en.pdf](http://www.legislation.gov.uk/asp/2008/5/pdfs/asp_200885_en.pdf) The Bill leading to the 2008 Act was introduced in the Scottish Parliament on 25 October 2007 and its legislative history and relevant documents are available at the Parliament's website: <http://www.scottish.parliament.uk/parliamentarybusiness/Bills/16454.aspx>

<sup>35</sup> AIDS (Control) Act 1987, S 1 [http://www.legislation.gov.uk/ukpga/1987/33/pdfs/ukpga\\_19870033\\_en.pdf](http://www.legislation.gov.uk/ukpga/1987/33/pdfs/ukpga_19870033_en.pdf)

<sup>36</sup> <http://www.scotland.gov.uk/Publications/2007/03/30093343/0#> at Chapter 4, paragraph 1.5

HIV is an example) in the new notification system.<sup>37</sup> The arguments against a notification requirement for HIV or any other STIs appear to have been based on considerations of confidentiality and concern that it would have an overall negative effect on their surveillance. The point is not referred to in the Policy Memorandum to the subsequent Public Health (Scotland) Bill nor was it specifically explored during the Health and Sport Committee hearings, although there was some related discussion.<sup>38</sup>

**3.24** Part 2 of the Schedule to the Bill as introduced included on the list of notifiable organisms to be reported by diagnostic laboratories, 'any other clinically significant pathogen found in blood'. In its Stage 1 Report on the Bill, the Health and Sport Committee expressed its concern that this form of words could give rise to problems if directors of laboratories were, for example, to decide that HIV should be reported. In particular, it would compromise reassurances being given to people with STIs that confidentiality would be maintained. The words in question were removed by way of amendment during the passage of the Bill. The 1987 Act, in so far as it extended to Scotland, was repealed by the 2008 Act with effect from 1 January 2010. Under the 2008 Act, HIV/AIDS remained not listed either as a notifiable disease or as an organism.

**3.25** The regime established by the 2008 Act is relatively untried. Some parts of it are novel and it will take time to develop experience of it. For example, the scope of the requirement to notify 'Health Risk States' in particular is novel and may become clearer in time. The Inquiry has not investigated the operation of the current legislation, and it would be inappropriate to comment on it further.

**3.26** As matters stood during the material period up to 1991, the provisions for notification were not effective as a means of informing relevant medical authorities of the prevalence of infection with any relevant disease. For the purposes of the Inquiry it has been necessary to use other sources of information to attempt to paint a picture of the position as it emerged.

### **Patients with bleeding disorders infected with Hepatitis C as a result of treatment with blood products**

**3.27** The first group of patients to be considered is referred to in paragraph 3.2, item i, and consists of patients with bleeding disorders, primarily haemophilia, who were exposed to infection with Hepatitis C through their treatment with blood products. Determining the number of patients exposed to HCV as a result of their treatment by the NHS in Scotland is not straightforward because several sources of data are available, each reporting slightly different numbers. It has been possible to compare these and, to a great extent, reconcile the differences.

#### *Databases of patients with bleeding disorders*

**3.28** From the early 1950s a UK haemophilia register of anonymised data was established and maintained in Oxford in the form of a card index. The register was initially funded by the Medical Research Council.<sup>39</sup> It was taken over by the United Kingdom Haemophilia Centre Directors' (later 'Doctors') Organisation, (the UKHCDO) in about 1968. At the outset,

<sup>37</sup> [www.scotland.gov.uk/Publications/2007/03/30093343/0#](http://www.scotland.gov.uk/Publications/2007/03/30093343/0#) at Chapter 5, paragraph 2.4

<sup>38</sup> <http://archive.scottish.parliament.uk/s3/committees/hs/or-08/he08-0402.htm#Col529> at column 551 – 'Sexually transmitted diseases have been left off the list – I gather that that is because the Government does not want to inhibit people coming forward for treatment ...'

<sup>39</sup> Professor Ludlam – Day 14, page 53

there were widely-held reservations among haemophilia clinicians about the registration of information about patients. These reservations often related to confidentiality. The issue came to a head at a meeting of the UKHCDO in November 1979. It was resolved that the project should continue.<sup>40</sup> The database comprises information collected from all UK haemophilia centres. In practice, Scottish Haemophilia Directors returned anonymised data to Oxford as part of the national database and that arrangement has continued.

**3.29** In the meantime, it was proposed that the Scottish Home and Health Department (SHHD) should take over the similar register of patients with bleeding disorders that had been maintained for Scotland. There were objections, however, concerning the propriety of a central register containing the names and addresses of patients. Some patients had been concerned that there might be leakage of information, and it was agreed at a joint meeting of the SNBTS and Haemophilia Directors on 24 January 1977, that this desire for confidentiality should be respected. The cards were distributed to the Regional Haemophilia Directors to be held locally.<sup>41</sup>

**3.30** It appears that thereafter data were held by Haemophilia Centre Directors and Regional Transfusion Directors in Scotland on locally devised systems which were not necessarily compatible as between transfusion practitioners and haemophilia clinicians.<sup>42</sup> It is likely that the Scottish Haemophilia Centres had held local databases of patients prior to 1977 and continued with these without modification in the new regime.

**3.31** Thus, in the 1970s there came to be two parallel databases of patients: informal local indices at each hospital where blood disorder patients were treated and a national, increasingly anonymised, database maintained by the UKHCDO to which each treatment centre sent information. This state of affairs was formalised at UK level at the end of 1979. Locally, Haemophilia Directors and other clinicians continued to hold data relating to their own patients.

**3.32** There were, and remain, limitations on the accuracy of the UKHCDO data. Capturing data concerning all of the patients proved to be a slow business at least until 1980. Quite apart from the resistance to disclosing information, already noted, patients often exercised a choice to be managed at local hospitals even where there was not a dedicated haemophilia facility. Some needed persuasion to accept the inconvenience of going to a bigger centre, which might involve travelling considerable distances, even though care might be better there.<sup>43</sup> As explained by the UKHCDO, the rapid increase in numbers of registered patients in the first decade after the database was established, suggested that early registration data may be incomplete.<sup>44</sup>

**3.33** The problem relating to the earlier years was illustrated by Dr Hay with reference to Glasgow. Between 1970 and 1980, the Glasgow registrations for haemophilia at the UKHCDO, unadjusted for duplicate registrations, are as set out in Table 3.1.<sup>45</sup>

<sup>40</sup> Minutes of the Tenth Meeting of the UK Haemophilia Centre Directors held in Oxford on Tuesday and Wednesday, 20th and 21st November, 1979 [LOT.003.4058] at 4071

<sup>41</sup> Note of Meeting of Directors of the Scottish National Blood Transfusion Service and Haemophilia Directors on 24 January 1977 [SNB.001.5033]

<sup>42</sup> For example, in the west of Scotland in 1977 donor information was kept on coded computer tapes, with the master file held in BTS headquarters. That reflected, for the time, a fairly advanced use of technology. The minute of the meeting does not disclose whether others followed a similar course. Until the early 1980s blood transfusion records and blood bank records in hospitals tended generally to be in paper form. Paper records were more vulnerable to loss, destruction or accidental discard.

<sup>44</sup> Ibid, pages 18–19

<sup>45</sup> Preliminary Report: Appendix 1 – UKHCDO Data [PEN.013.1433]

**Table 3.1: Count of Glasgow patients at five-yearly intervals**

		Haemophilia A	Haemophilia B	Totals
1970	Royal Infirmary	71	7	78
	Royal Hospital for Sick Children	3	0	3
				81
1975	Royal Infirmary	102	15	117
	Royal Hospital for Sick Children	8	0	8
				125
1980	Royal Infirmary	196	52	248
	Royal Hospital for Sick Children	55	14	69
				317

**3.34** The increase in each case was far in excess of the birth-rate or any other factor indicating real growth over the period. This was a period when mortality was beginning to be offset by the benefits of concentrate therapy, and that may to some extent have increased the numbers of patients remaining on the register. However, few data were submitted during the early part of the period. Haemophilia care was fragmented in the west of Scotland at this time. Many patients were managed at smaller hospitals around the south west of Scotland at the beginning of the period but, with the advent of increasingly effective treatment, they gradually gravitated towards the centre. The Glasgow pattern is highly unlikely to have been unique, and the lack of reliability of early data must have been common.

**3.35** It appears reasonable to avoid speculation as to probable numbers and to treat the 1970 registrations as wholly unreliable in estimating numbers of patients treated and therefore exposed to some level of risk. It also appears reasonable to accept that the number of 1975 registrations would require to be modified to reflect the probability that the process of gathering patients into the reporting system was continuing and had not completely captured all relevant patients. The numbers recorded in the UKHCDO database from 1980 (as adjusted) are reasonably firm.

**3.36** A continuing problem relates to the 'hub and spoke' care model which was developed and which has resulted in some patients being registered and managed at more than one centre.<sup>46</sup> The data required to be adjusted to exclude duplications. Investigation by the UKHCDO subsequent to the publication of the Preliminary Report uncovered inaccuracies in the data provided to, and published by, the Inquiry. The Inquiry is grateful to the UKHCDO for the work carried out to check the database, internally and against extant original records, and to provide adjusted data. The database, which has improved over time and now provides a wealth of relevant data, has become the primary source of published information on exposure to risk among this class of NHS patients, and their treatment thereafter.

### *UKHCDO and Scottish Haemophilia Directors' data on patients with bleeding disorders*

**3.37** The primary sources of published up-to-date data are the UKHCDO Bleeding Disorder Statistics for April 2010 to March 2011, and April 2011 to March 2012. The adjusted numbers of patients with clotting factor deficiencies in Scotland known to the

<sup>46</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry, April 2012* [PEN.019.0927] at 0956

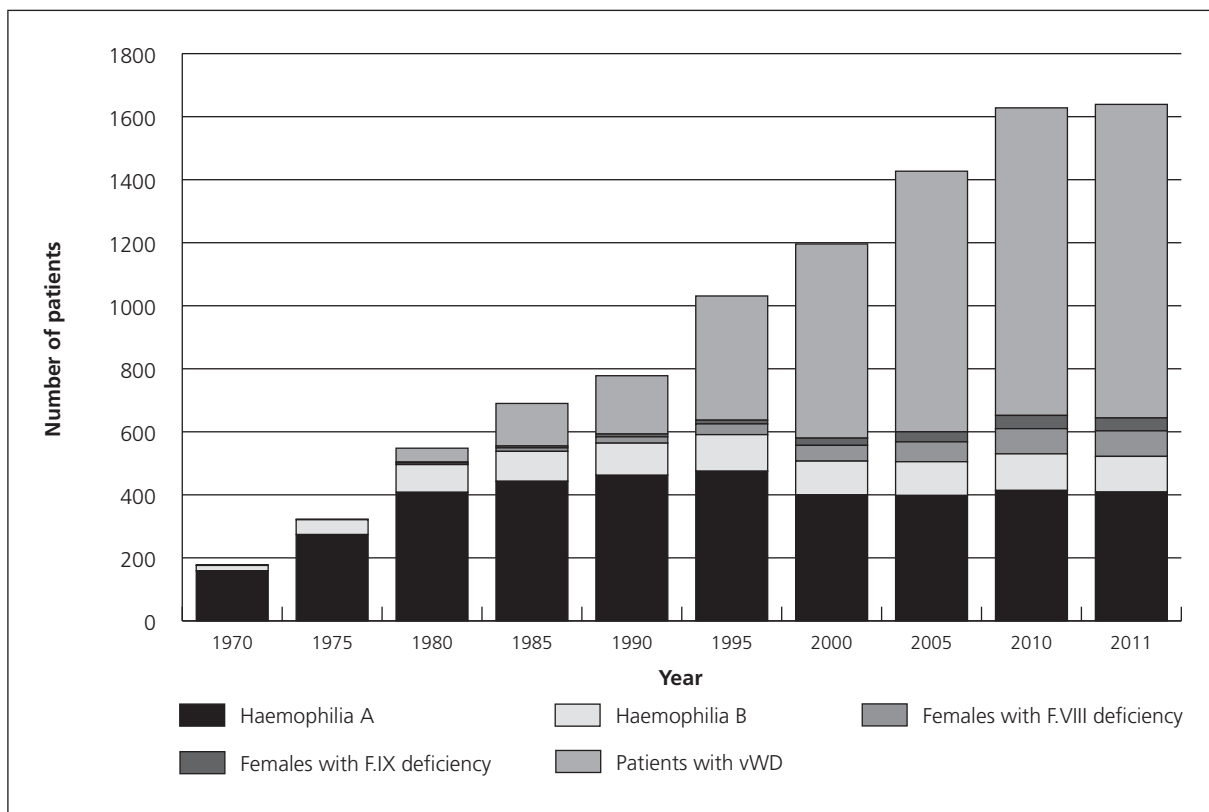

UKHCDO and cross-checked with Scottish Haemophilia Centres, at April 2012 (subject to the reservations about the accuracy of data before 1980 already noted) are as set out in Table 3.2.<sup>47</sup>

**Table 3.2: Count of registered patients: All Scottish centres**

	Haemophilia A	Haemophilia B	Females with F.VIII deficiency	Females with F.IX deficiency	vWD	Total
1970	159	17	0	0	2	178
1975	274	47	0	0	2	323
1980	408	88	5	3	44	548
1985	443	95	11	6	135	690
1990	462	102	20	9	185	778
1995	475	116	34	12	394	1031
2000	400	107	50	23	616	1196
2005	398	107	63	32	827	1427
2010	414	116	80	42	976	1628
2011	409	113	81	41	995	1639

**3.38** The pattern of individuals registered with each condition is illustrated in Figure 3.1.

**Figure 3.1: Individuals with bleeding disorders registered in Scotland**

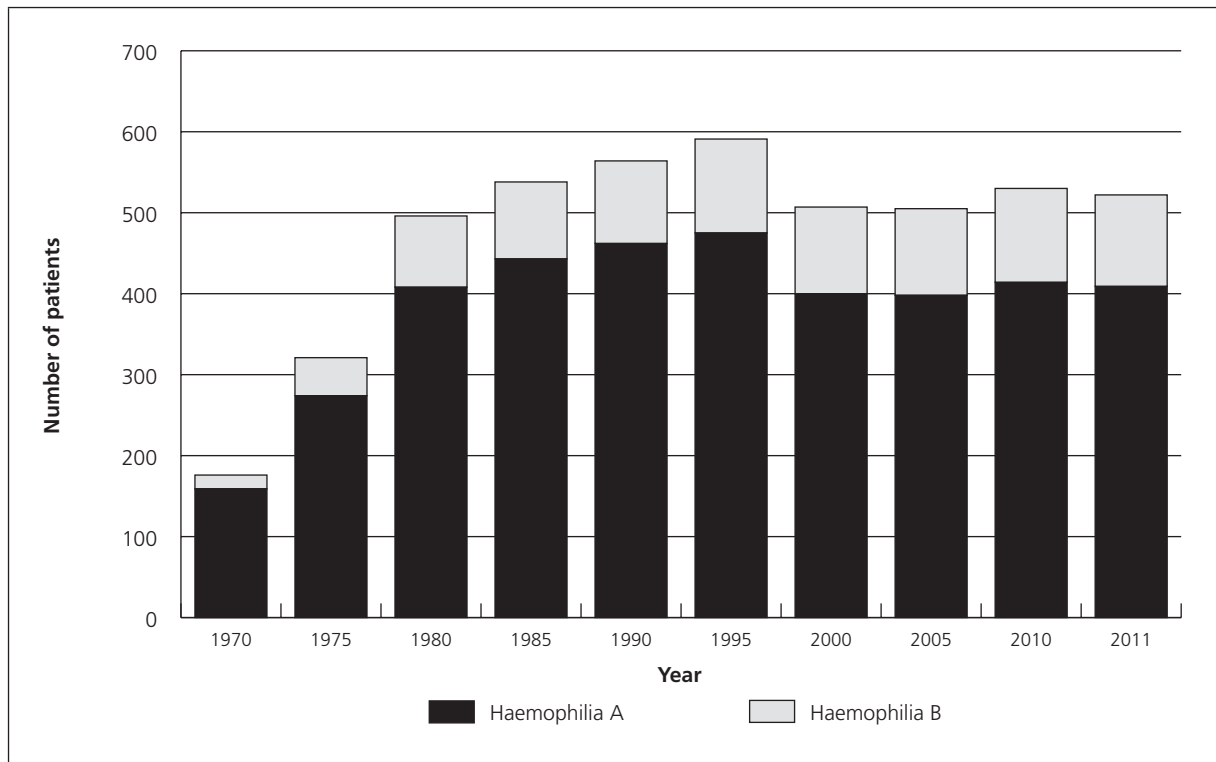

<sup>47</sup> The data are extracted from the UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry, 2012*, Table 2 [PEN.019.0927] beginning at 0956

**3.39** Setting aside early inaccuracies, the numbers of Haemophilia A and Haemophilia B patients registered are reasonably consistent over the period from 1980. The trends in registered female and von Willebrand's disease (vWD)<sup>48</sup> patients cannot be explained in terms of natural growth in prevalence of the diseases. Three factors may have contributed:

- Increasing sophistication in the diagnosis of mild forms of the diseases.
- Greater diligence in reporting to UKHCDO.
- A growing tendency, in operating the hub and spoke model, for peripheral haemophilia centres and other, non-specialist, hospital units to refer patients with these less serious conditions to haemophilia centres in the major cities.

Isolating the numbers for individuals with Haemophilia A and B, the pattern is illustrated in Figure 3.2.

**Figure 3.2: Individuals with Haemophilia A and Haemophilia B registered in Scotland**

**3.40** These data are accepted as accurate for the purposes of this report. The data for patients with Haemophilia A and Haemophilia B provide a reasonable view of the majority of patients potentially exposed to risk in and after 1980, since registration would have followed attendance at a haemophilia centre, whether the patient was treated or not. The numbers cannot be treated as completely accurate, since it is likely that some patients (particularly mildly and moderately affected patients) still preferred to receive the required treatment locally, rather than at what may have been a remote haematology clinic. Consequently, such patients were not referred to a haemophilia centre, and were not registered with UKHCDO.

<sup>48</sup> Von Willebrand's disease is an inherited blood disorder with symptoms of spontaneous bleeding similar to haemophilia, although significantly affecting women as well as men (unlike haemophilia).

**3.41** The UKHCDO Bleeding Disorder Statistics for April 2010 to March 2011<sup>49</sup> show the total numbers of UK patients currently on the register for that year, and provide a basis for comparison of the Scottish data in Table 3.2 with the position in the rest of the UK, as set out in Table 3.3.<sup>50</sup>

**Table 3.3: Count of registered patients: All Scottish centres and all other centres – 2011**

	Haemophilia A	Haemophilia B	Females with F.VIII deficiency	Females with F.IX deficiency	vWD M + F	Total
All centres	5367	1133	1116	345	9112	17,073
Scotland	409	113	81	41	995	1639
Centres other than Scotland	4958	1020	1035	304	8117	15,434
Scotland/ all centres %	7.62	9.97	7.26	11.88	10.92	9.6
Scotland/ rest of UK %	8.25	11.08	7.83	13.49	12.6	10.62

**3.42** It is not possible to make a similar comparison for earlier years, since the Scottish data before 2011 have been fully revised (for the purpose of informing this Inquiry) to avoid duplication, while the figures for the rest of the UK have not. The figures available for the UK as a whole are set out in Table 3.4.

**Table 3.4: Count of registered patients: All UK centres**

	Haemophilia A	Haemophilia B	von Willebrand's disease	Total
1987	5195	982	2215	8392
1990	5339	1055	2688	9082
1995	5413	1133	4105	10,651
2000	5385	1165	5955	12,505
2005	6012	1276	7718	15,006
2009	6480	1372	9265	17,117

**3.43** The lack of fit of the von Willebrand's data with the data for Haemophilia A and B is as clear for the UK as it is for Scotland. The trends in growth of registered von Willebrand's disease appear generally to reflect the sensitivity of the results to variations in reporting and other factors referred to above. There is no other rational explanation for the apparent explosion in growth of the disease in Scotland, or in the UK as a whole. It is known that, historically, the disease was under-diagnosed. It is now recognised to be the most common bleeding disorder, but it is usually a mild disorder. Most patients were, and still are, more likely to be managed locally and outside the specialist haemophilia service.

<sup>49</sup> UKHCDO (2011) *UK National Haemophilia Database Bleeding Disorder Statistics for April 2010 to March 2011*. Available: <http://www.ukhcdo.org/docs/AnnualReports/2011/UKHCDO%20Bleeding%20Disorder%20Statistics%20for%202010-2011.pdf> Last Accessed 3 February 2015

<sup>50</sup> Data for 2011–2012 are available in the UKHCDO Annual Report for that year. However, the data for Scottish registrations relate at latest to 2010–2011. Differences are small and are unlikely to alter significantly the ratios of Scottish to UK patients.

In that case they may not be reported to the National Haemophilia Database at all.<sup>51</sup> These data continue to be revised. For present purposes they are accepted as an accurate reflection of the information available to the UKHCDO and the Scottish Haemophilia Directors.

### *Numbers of bleeding disorder patients infected with Hepatitis C*

#### UKHCDO – Initial research

**3.44** All patients with coagulation disorders were exposed to risk if they required treatment with blood, blood components or blood products, before the introduction of routine screening of blood donations for HCV and effective virus inactivation. Cryoprecipitate was commonly associated with transmission of HCV infection. Factor concentrates were almost universally associated with transmission of HCV. This was the case whether the concentrates were produced by commercial companies or by the NHS and whether a patient received a single treatment or multiple treatments.<sup>52</sup> An SNBTS Factor IX concentrate, effectively heat-treated to inactivate the virus, was released in October 1985. By 1987 effective virus inactivation had been introduced for PFC's Factor VIII concentrate, and manufacture of concentrates by the older processes had stopped. In each case, until effective heat treatment was introduced it is likely that almost all haemophilia patients who received treatment in the 1970s and most of the 1980s with factor concentrates made from the large pools of plasma, contracted Hepatitis C.

**3.45** Data of patients' use of factor concentrates were held in the National Haemophilia Database, and the UKHCDO provided an estimate of the number of patients exposed to Hepatitis C on the basis of their exposure to concentrate administered in a Scottish Haemophilia Centre. A UKHCDO statistics report was produced in April 2012 following additional work by the organisation and by the individual haemophilia centres in Scotland to enter additional data into the database, to correct inaccuracies in data previously entered and to cross-check all of the data entered against the UKHCDO's paper archive and against the information held by the Scottish centres.<sup>53</sup> It was acknowledged that there were weaknesses in the exercise. Quite apart from inherent problems leading to duplication of entries, the data were only as good as the submissions on which they were based. Further, in his introduction to the updated report of April 2012, Dr Hay stated:

Inevitably, given the time that has elapsed since the period of interest, there remain gaps and many centres no longer have records stretching that far back and have not been able to cross-check everything. Nevertheless, we believe that the data presented is now as complete and as accurate as we are able to make it.<sup>54</sup>

**3.46** The UKHCDO extracted data from the National Haemophilia Database as adjusted, which indicated that 296 living patients and 216 deceased patients treated at Scottish centres had been exposed to HCV, giving a total of 512.<sup>55</sup> Within that total, research

<sup>51</sup> Dr Hay – Day 8, page 22

<sup>52</sup> Ibid pages 33–35; *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at 0019 and 0020, paragraph 4; Dr Tait – Day 14, page 84; literature referred to in paragraph 7.4, footnote 3 of the Preliminary Report.

<sup>53</sup> The further work undertaken by the UKHCDO in conjunction with the Scottish Haemophilia Centres is more fully set out in Dr Hay's introduction to the updated UKHCDO report, UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012 [PEN.019.0927] at 0933

<sup>54</sup> Ibid [PEN.019.0927] at 0934

<sup>55</sup> Ibid [PEN.019.0927] at 0985, Table 8. There is an error in the summation of the figures. The figure for Inverness patients who were alive in 2011 should be 26.

uncovered a number of duplications. Excluding these, the adjusted totals provided by the UKHCDO were 254 living patients and 193 deceased patients, a total of 447. That was the position at April 2012 when the UKHCDO produced its updated report.<sup>56</sup> Table 7 in the report provided a diagnostic breakdown of patients known to the UKHCDO as at 2011, both alive and dead, who were thought to have been infected with Hepatitis C by virtue of exposure to clotting factor concentrates, prior to effective virus inactivation (1987). The data are summarised below in Table 3.5.

**Table 3.5: Estimate of the number of patients exposed to Hepatitis C based on historical clotting factor concentrate exposure from a Scottish Haemophilia centre: April 2012 Survey**

Diagnosis	Alive	Dead
Haemophilia A	165	158
Haemophilia A with liver transplant	1	3
Acquired Haemophilia A	2	3
Haemophilia B	58	19
Females with VIII deficiency	7	0
Females with IX deficiency	4	0
von Willebrand's disease	16	10
Temporary coagulation defect, now normal	1	0
Totals	254	193
Total number exposed	447	

**3.47** These numbers reflected the adjustments to UKHCDO raw data required to exclude double counting where patients were treated at more than one centre and returned by each.<sup>57</sup> The total number of deaths from all causes in the population, 193, has been cross-checked with the Office of National Statistics. The number of liver-related deaths appears to be 21.<sup>58</sup>

**3.48** The figures tabulated are based on known concentrate exposure, believed to be solid data. The strengths of the exercise are:

- The data were collected contemporaneously rather than retrospectively and so the documentary evidence on which they were based was as complete as it was ever going to be. In some cases the original local documentation had been destroyed and the National Haemophilia Database was the only available evidence.
- The Database was compiled from data for each patient submitted by the managing centre.
- The UKHCDO had data on patients who died before the advent of testing and data on patients subsequently lost to follow-up for which there was now no information available directly from the centres.<sup>59</sup>

<sup>56</sup> Ibid [PEN.019.0927]

<sup>57</sup> Ibid [PEN.019.0927] at 0981

<sup>58</sup> Ibid [PEN.019.0927] at 0986, Table 9

<sup>59</sup> Dr Hay's letter dated 16 January 2013, page 5 [PEN.019.1319] at 1323

**3.49** Dr Hay commented that the estimate of 447 patients exposed to Hepatitis C on the basis of concentrate therapy was probably an under-estimate of the total population at risk. It did not include provision for the number of patients likely to have been exposed through treatment with blood, blood components or cryoprecipitate, rather than concentrates.<sup>60</sup> In oral evidence, Dr Hay expanded on this:

The other thing you need to recognise about these figures is that they are likely to be conservative because they are based on our records of concentrate exposure and some patients may only have been treated with blood components, plasma or cryoprecipitate, and we feel that our data on that exposure may be incomplete ...

So we have assumed that everyone who has had concentrate will have been exposed to Hepatitis C if they were treated during the period of risk. But they may in fact have contracted Hepatitis C before their first exposure to concentrate from treatment with blood components, particularly if they have a severe bleeding disorder and require regular treatment.<sup>61</sup>

**3.50** The results were not presented as definitive.

### Scottish Haemophilia Centre Directors

**3.51** The Scottish Haemophilia Centre Directors provided the Inquiry with separate estimates of the number of patients registered with Scottish Haemophilia Centres who were infected with the Hepatitis C virus as a result of their treatment with blood products (coagulation factor concentrate, cryoprecipitate or fresh frozen plasma) in February 2011 and March 2013. Dr Campbell Tait, Director of the Haemophilia Centre at Glasgow Royal Infirmary, explained that in February 2011 the Scottish Directors used UKHCDO data relating to patients at risk of having contracted Hepatitis C as a result of their treatment between 1970 and 1988,<sup>62</sup> and HCV status data from patient records held at Scottish Haemophilia Centres.<sup>63</sup> The Scottish Haemophilia Directors excluded from the UKHCDO data any patient whose first treatment was outwith Scotland, any patient known to have tested negative for Hepatitis C post-1991 (76 patients) and any patient whose sole treatment at a Scottish Haemophilia Centre during the relevant period was with non-plasma based products (for example synthetic agents such as Desamino-D-arginine-vasopressin (DDAVP)). The Directors then added a small number of patients known by Scottish Haemophilia Centres to be HCV positive, most likely from treatment in Scotland, but who did not appear on the list from the UKHCDO.

**3.52** In summary, comparison of the outcomes of the Scottish Haemophilia Centre Directors' study in February 2011<sup>64</sup> and the April 2012 UKHCDO survey appeared to show material differences in the numbers of HCV-infected patients with Haemophilia A or B and patients with von Willebrand's disease. This information is set out in Table 3.6.

<sup>60</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012, page 51 [PEN.019.0927] at 0983. The Inquiry understands that the UKHCDO statistics report categorises cryoprecipitate as a 'blood component' rather than as 'concentrate'.

<sup>61</sup> Dr Hay – Day 8, pages 41–42

<sup>62</sup> *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] (this methodology superseded an earlier methodology, [PEN.001.0057].)

<sup>63</sup> The start date of 1970 is a few years before the introduction and widespread use of factor concentrate in Scotland. Having said that, there may well have been patients with haemophilia who were infected with Hepatitis C in the 1960s as a result of treatment with cryoprecipitate or other blood products (made from much smaller pools of plasma than factor concentrate in the 1970s and 1980s). These patients will not be included in the estimates provided by the Scottish Haemophilia Directors.

<sup>64</sup> *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at page 0018

**Table 3.6: Comparison of the Scottish Haemophilia Centre Directors' study and the UKHCDO survey**

Diagnosis	UKHCDO survey: April 2012	Scottish Directors' study: February 2011
Haemophilia A	332	303
Haemophilia B	77	68
von Willebrand's disease	26	62
Other coagulation disorders	12	26
Total	447	459

**3.53** Dr Tait commented on weaknesses in the Scottish Directors' study at that stage:

Determining whether patients remaining on the list, who have never had an HCV antibody test undertaken, had NANB or HCV is very difficult. Some of the patients are dead and have no remaining blood sample that could be tested for HCV. Otherwise clarification will require detailed review of historical medical case notes (which in many centres no longer exist). It is possible that some of these patients have undiagnosed HCV .... Therefore it is the intention of the Scottish Haemophilia Centres to, where possible, trace these 'unknowns' and suggest HCV testing where appropriate.

Some of these patients only had a very few treatments in Scotland, and were probably visitors who if they did have HCV would likely have contracted it outwith Scotland – but we have insufficient information to be certain.

Therefore the final list supplied to [the Inquiry] represents the estimated maximum number of bleeding disorder patients who contracted HCV from treatment in Scotland.<sup>65</sup> The accuracy of the data is limited by the assumptions made. There are small numbers of patients who received PFC Factor VIII before July 1987 who are HCV negative and the numbers of patients infected as a result of cryoprecipitate therapy only, are likely to be overstated.<sup>66</sup>

**3.54** HCV negative patients would comprise patients exposed to the virus but were not infected, and patients who were infected but had cleared the virus. In their methodology statement, the Scottish Haemophilia Directors indicated that they had assumed that all patients treated with coagulation factor concentrates or cryoprecipitate prior to July 1987 contracted Hepatitis C, unless they had subsequently been tested negative.<sup>67</sup> On that basis, up to 62 von Willebrand's patients may have contracted HCV in Scotland. The UKHCDO estimated that 26 von Willebrand's patients treated at Scottish Haemophilia Centres contracted HCV infection.<sup>68</sup>

<sup>65</sup> Elsewhere, Dr Tait described the estimate of 459 patients who contracted HCV as a result of treatment in Scotland as a 'cautious overestimate': *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at 0018, paragraph 1

<sup>66</sup> Ibid [PEN.013.0016], at 0017 and 0018, paragraphs 10–12

<sup>67</sup> Ibid at [PEN.013.0016]

<sup>68</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry, 2012* [PEN.019.0927] page 52.

**3.55** In addition to estimating the maximum number of NHS coagulation disorder patients infected with Hepatitis C, the Scottish Haemophilia Directors provided an estimate of the minimum number infected as a result of treatment in Scotland. In their February 2011 study that minimum number was 314, on the basis that 314: 'represents the numbers that we know who are or have been Hepatitis C antibody positive, plus a small number who were never tested but we have evidence that they clinically suffered an episode of non-A non-B hepatitis'.<sup>69</sup> That estimate was therefore based on hard data.

**3.56** The totals advised by the UKHCDO and the Scottish Haemophilia Directors at this stage were broadly consistent with the advice received by Lord Ross' Expert Group<sup>70</sup> that approximately 500 haemophilia patients were likely to have become infected with Hepatitis C as a result of treatment in Scotland with blood products.<sup>71</sup> However, the initial exercises not only produced figures that differed numerically; more significantly it identified differences in the nature of the data available and the assumptions used. Dr Hay of the UKHCDO and Dr Tait, representing the Scottish Haemophilia Directors, were asked to reconsider their evidence. They did so and each produced further information.<sup>72</sup>

**3.57** Dr Tait's statement of 8 January 2013, revealed differences in underlying data among the various estimates provided. The UKHCDO based the estimate of likely HCV-infected patients (447) on the assumption that the virus was transmitted on the patient's first exposure to clotting factor concentrates. The UKHCDO database did not include information on patients' known HCV status, positive or negative. In his evidence, Professor Goldberg had explained that HPS was aware of 351 individuals who had received blood factor concentrates and who had been diagnosed as Hepatitis C antibody positive.<sup>73</sup> These data related solely to bleeding disorder patients in Scotland who had tested positive for anti-HCV and who were likely to have acquired infection through blood product exposure. The HPS data did not distinguish patients according to the country in which it was likely they were infected, and did not take account of any patients who had died before antibody testing became available in about 1990. A recent review of the Scottish Haemophilia Directors' data had shown that among the cohort of 351 infected patients identified in Scotland there were 46 who were thought to have contracted HCV from prior treatment outwith Scotland. The Scottish Haemophilia Directors' own exercise had revealed 15 patients not included in the UKHCDO list; accordingly the UKHCDO figure could be adjusted to 462, which was similar to the Directors' figure of 459.

**3.58** Having reviewed the data in 2013, Dr Tait advised on the range:

- A minimum number of 300 to 305 bleeding disorder patients known to have contracted HCV (as assessed by HCV antibody positivity) through haemostatic treatment in Scotland.

<sup>69</sup> Dr Tait – Day 14, page 83 and *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at 0017, paragraph 8

<sup>70</sup> See paragraph 3.173

<sup>71</sup> Final Report of Lord Ross' Expert Group, March 2003; paragraph 4.8. <http://www.scotland.gov.uk/Publications/2003/03/16844/20519>. This advice appears to have been received from the UK Haemophilia Directors (letter dated 24 July 2002 from Dr Brian McClelland to Mr Bob Stock, Special Advisor [SGH.005.7201] at 7202). While it is not clear how that figure was arrived at, it may have been based on the approximate number of patients with bleeding disorders in Scotland who received treatment with concentrate during the relevant period.

<sup>72</sup> Dr Hay's letter dated 16 January 2013: [PEN.019.1319] Dr Tait's response to further questions on statistics, 8 January 2013: [PEN.019.1306]

<sup>73</sup> Professor Goldberg – Day 6, pages 116–119. See also Professor Goldberg's statement on statistics relating to haemophilia patients infected with HCV dated 1 February 2011 [PEN.001.0206], questions 1 and 2 at 0206 and accompanying tables at 0207. A breakdown of (a) the health board area where each patient resides or, if not known, where the positive sample was taken, (b) the reported blood disorder and (c) the year of the earliest specimen positive for HCV antibody is shown at [PEN.001.0206] at 0207.

- An estimated upper figure of 459 to 462, based on the Scottish Haemophilia Directors' estimate of 459 patients and the UKHCDO figure of 447 increased by 15 patients not on the UKHCDO list who were known to the Scottish Directors to be anti-HCV positive, most likely due to treatment in Scotland.<sup>74</sup>

**3.59** On 26 March 2013 the Inquiry received an updated version of the Scottish Haemophilia Directors' calculations as prepared for publication.<sup>75</sup> The Inquiry is grateful for the additional work carried out. In its final form, the paper reported that 455 patients with bleeding disorders were estimated to have been infected with HCV by coagulation factor provided by NHS Scotland before 1989. Of these, 440 were agreed with the updated UKHCDO database and 15 further patients were known to Scottish Haemophilia centres but did not appear in the list prepared by UKHCDO.

**3.60** In order to chart outcomes after infection, Khan and colleagues reported on a second cohort of 302 patients, of whom 255 were included in the revised total of 455 patients infected in Scotland and 47 were infected elsewhere but followed up in Scotland.<sup>76</sup> Of the 302 patients, 293 had Polymerase Chain Reaction (PCR) testing performed and of that 293, 51 patients (17.4%) cleared the infection naturally. Of the group of 293 patients who were tested, 243 were PCR positive at some stage. One of those 243 patients was documented as being positive on one occasion and tested negative thereafter despite having no treatment, giving a total of 51 patients with natural clearance. Further, of those 243 patients, 103 had by February 2012 completed combination anti-viral treatment with ribavarin and alpha-interferon or pegylated interferon. The overall sustained viral response for combination therapy was 38.8%.<sup>77</sup> Fourteen of the 302 (4.6%) had a diagnosis of hepatocellular cancer, and 10 of those patients had died at February 2012. By the same date, 11 patients had undergone liver transplantation (seven for liver failure and four for liver cancer) and seven of them were still alive.<sup>78</sup>

#### UKHCDO – Further research

**3.61** Following the 2012 report (and as anticipated in it), the UKHCDO began a more detailed and systematic HCV look-back study, partly stimulated by the Inquiry. In collaboration with each haemophilia centre, including those in Scotland, data were collected from haemophilia centres on individual patients' Hepatitis C test results. In a letter dated 16 January 2013,<sup>79</sup> Dr Hay explained that at January 2013, and with the UKHCDO HCV look-back still incomplete, a very preliminary overall estimate of the numbers infected with HCV should first include the 447 patients (alive and dead) exposed to infection by concentrate, as set out in the earlier exercise. Dr Tait's review then noted that there were 15 patients known by the Scottish Haemophilia Directors to be HCV positive, most likely due to treatment in Scotland, who were not included in the UKHCDO list of 447 patients. Adjusting for those increased the UKHCDO figure to 462. The amended and additional data provided by the UKHCDO was not available when the Scottish Haemophilia Directors updated their estimates as set out in the paper by Khan and colleagues.

<sup>74</sup> Dr Tait's response to further questions on statistics, January 2013 [PEN.019.1306] at 1307

<sup>75</sup> Khan *et al*, 'Assessment of hepatitis C infection and outcomes in the Scottish haemophilia population', *Haemophilia*, 2013; 19:870–875 [PEN.019.1336] This version contained minor adjustments to figures previously provided, together with new information about treatment and follow-up.

<sup>76</sup> *Ibid* [PEN.019.1336] at 1341

<sup>77</sup> *Ibid* [PEN.019.1336] at 1343

<sup>78</sup> *Ibid* [PEN.019.1336] at 1342

<sup>79</sup> Dr Hay's letter dated 16 January 2013 [PEN.019.1319]

**3.62** Dr Hay provided a further table showing a diagnostic breakdown of 85 Scottish patients exposed only to blood components (plasma, cryoprecipitate and blood or platelet concentrates) and not exposed to (factor) concentrates during the period of risk.<sup>80</sup> Not all of the patients in this group would have become infected with HCV.

**Table 3.7: Estimate of the number of patients in each diagnostic group exposed to Hepatitis C based on historical plasma exposure from a Scottish Haemophilia centre (January 2013; based on first 20% data only)**

	Alive	Dead
Haemophilia A	18	9
Haemophilia B	1	2
Females with Factor VIII deficiency	4	0
Females with Factor IX deficiency	3	0
von Willebrand's disease	33	6
Factor VII deficiency	1	0
Factor IX deficiency	1	0
Factor XII (Hageman) defect	1	0
Factor XIII deficiency	1	0
Fibrinogen deficiency	1	0
Platelet defects (misc)	2	0
Unclassified	0	1
Temporary coagulation defect, now normal	1	0
Total	67	18

**3.63** On the basis of data available in the look-back exercise as a whole, Dr Hay estimated that patients selected in this way would have an 18.6% probability of HCV infection. This would add a further 16 patients to the UKHCDO number. Of that group of 16, chronic HCV infection would be expected in 10-12.<sup>81</sup> Whilst this approach permitted him to estimate the proportion of that group exposed to HCV, it did not permit him to identify individual patients likely to have been infected.<sup>82</sup> This look-back study was ongoing at the time and Scottish centres had by then submitted only 20% of the data requested. More accurate data might therefore become available on completion of the exercise.<sup>83</sup>

**3.64** As noted already, it is highly likely that almost all of the patients exposed to risk in the course of their treatment with factor concentrates before effective heat treatment was introduced, will in fact have had Hepatitis C virus transmitted to them at some time. However, current understanding of the natural history of infection with HCV indicates that a percentage of patients will either not have developed an HCV infection or will have cleared the virus spontaneously. Where that is due to a protective immunity or to the individual's other genetic characteristics, the same outcome will follow a subsequent infection.<sup>84</sup> Estimates vary, as indicated by the evidence noted so far.

<sup>83</sup> Ibid [PEN.019.1319] at 1324

<sup>84</sup> See Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.17

### *Discussion of the reported estimates*

**3.65** It is still not possible to achieve a satisfactory reconciliation of all available sources of data. The additional evidence of Dr Hay and of Dr Tait is accepted as providing the best estimates that can be made on the sources of information available. They provide a measure of reconciliation of the upper figures and therefore an indication of the likely extent of the problem. However, each has stated that the exercises now reported are continuing. The UKHCDO continues to refine its exercise. The Scottish Haemophilia Directors group continues to seek out and assess patients who have or may have received coagulation treatments prior to 1989–91 and who remain untested for HCV. It is a slow ongoing process.

**3.66** In the circumstances it is important to avoid underestimating the prevalence of HCV infection among blood disorder patients. While some percentage of those at risk may have avoided infection and others will have cleared infection spontaneously, these numbers cannot be known with any certainty. It seems safer to proceed on the basis that all of those at risk were infected. The UKHCDO estimate (as adjusted in conjunction with the additional data provided by Dr Tait) of 462 patients infected by concentrates is accepted on that basis. The number infected by blood components and plasma products is speculative at this stage. It is possible to estimate a number arithmetically, but any exercise is based on the selection of assumptions required for the calculation. The data gathered to date (20% of the data sought) are not a random sample and cannot be assumed to represent the whole class. So far, it appears that 16 patients can be added to the 462. It is not known what the remaining 80% of data will reveal and no provision is therefore made for any additional numbers of patients which may be generated.

### *Patients with bleeding disorders known to have been infected with Hepatitis C*

#### **Health Protection Scotland**

**3.67** Agencies other than UKHCDO recorded lower numbers of patients said to have been infected with HCV. As previously observed, Professor Goldberg gave evidence that HPS is aware of 351 individuals who had received blood factor concentrates and been diagnosed as Hepatitis C antibody positive.<sup>85</sup> For each of these individuals there was no information to indicate that blood factor concentrates had been received outside Scotland.

**3.68** Dr Tait suggested that the HPS data could be reconciled with the Scottish Haemophilia Directors' data. A review carried out in February 2012 by Dr Henry Watson of the Directors' 2007 review of HCV and its treatment in Scotland had identified, within the cohort of HCV-positive bleeding disorder patients, 46 persons who were thought to have contracted HCV from prior treatment outwith Scotland.<sup>86</sup> Adjusted for these patients, the HPS figure was reduced to 305, a close similarity to the Scottish Haemophilia Directors' figure for bleeding disorder patients known to be HCV positive from treatment in Scotland.<sup>87</sup>

**3.69** That is accepted. Yet it indicates that the HPS database presently captures, and is able to capture, only part of the relevant data. It provides clear evidence of the numbers found to be infected on testing at virology laboratories reporting to HPS. Of necessity that cannot cover patients who were never tested while they were alive. As shown in Table 3.5, UKHCDO data suggest that, by April 2012, 193 Scottish blood disorder patients exposed

<sup>85</sup> Paragraph 3.57

<sup>86</sup> Dr Tait's Response to further questions on statistics, 8 January 2013 [PEN.019.1306]

<sup>87</sup> Paragraph 3.55

to clotting factor concentrates before 1988 had died. Some might have been collected by retrospective testing of stored samples, but that would be of assistance only if there had been a systematic study of stored samples. There is no evidence of that having happened. Finally, as Professor Goldberg indicated, clinical information available to HPS is very limited in respect of the underlying diagnoses of those tested.<sup>88</sup>

### The Skipton Fund

**3.70** The Skipton Fund<sup>89</sup> advised that 231 patients with bleeding disorders living in Scotland who had received treatment with blood products and who were alive as at August 2003 had received payments from the Fund.

**3.71** HPS and Skipton data might suggest that the actual numbers infected may have been lower than the estimates already mentioned. However, some patients may well have been infected by the virus but cleared it prior to the availability of testing. Others may have died without infection with Hepatitis C being diagnosed. Some may survive without signs or symptoms of infection having been noted or brought to the attention of those keeping the relevant records.

**3.72** In the case of the Skipton Fund, it cannot be assumed that every person entitled to make a claim did so, and there is some concern about the reliability of a very small number of the claims admitted.<sup>90</sup> It would not be appropriate to adjust downwards the numbers of patients infected, as inferred from exposure to risk, on the basis of these recorded data.

**3.73** The Skipton data are consistent with the UKHCDO data on living patients: given the limits on accuracy in the exercise as a whole, the difference between 231 and 254 living patients is not significant.

### Hepatitis C – secondary transmission

**3.74** As discussed elsewhere in this Report, secondary transmission of Hepatitis C occurs relatively rarely from mother to baby and, even less commonly, as a result of sexual transmission.

**3.75** As regards possible secondary transmission of HCV from patients with bleeding disorders to their partners, Dr Tait said:

Where appropriate, during counselling, HCV infected haemophilia patients were informed about the suspected low risk of sexual transmission and that partners could be tested. This testing could be undertaken by the partner's GP, by the Haemophilia Centre or by the Infectious Disease Units in Glasgow and Aberdeen. In reality, only a small number of partners attended the Haemophilia Centres for testing (approximately 40 between Edinburgh and Glasgow), and I understand from colleagues that only 1 partner was found to be positive. Since the Haemophilia Centre staff had no direct contact with other partners, nor necessarily knew their identity, we have no information on their HCV status.<sup>91</sup>

<sup>88</sup> Professor Goldberg – Day 6, pages 99–100; Professor Goldberg's statement on statistics relating to haemophilia patients infected with HCV dated 1 February 2011 [PEN.001.0206] at 0211

<sup>89</sup> See paragraph 3.140

<sup>90</sup> See paragraph 3.146

<sup>91</sup> *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at 0018, paragraph 13

**3.76** Beyond noting that a minority of patients who contracted Hepatitis C as a result of infected blood or blood products may in turn have inadvertently infected others, it is not possible for the Inquiry to make an estimate of the number of individuals who may have contracted Hepatitis C as a result of secondary infection. It seems reasonable, however, to conclude that the number will have been very small and given the margins of error inherent in the overall estimation of patients at risk, would not make any material difference to assessing the scale of infection.<sup>92</sup>

### *Conclusions on HCV infection among patients with bleeding disorders*

**3.77** The most reliable estimates of the number of patients with bleeding disorders who were exposed to risk of infection with Hepatitis C as a result of their treatment in Scotland are those provided by the UKHCDO in collaboration with the Scottish Haemophilia Directors. Together, they have the best relevant data. Given their expertise in this area and the detailed investigation they have made of their respective records, their evidence is accepted as sufficiently reliable to support conclusions on numbers overall. Taking on board this ongoing work and using the data from the UKHCDO's ongoing look-back exercise, so far the best estimate appears to be about 478.

### *Hepatitis C as a cause of death among patients with bleeding disorders*

**3.78.** The Inquiry attempted to establish how many patients with bleeding disorders had died as a result of infection with HCV. The Inquiry was assisted by evidence from the Scottish Haemophilia Directors, the UKHCDO and Professor Goldberg of HPS.

**3.79** Dr Campbell Tait, on behalf of the Scottish Haemophilia Directors, stated:

To date we have not been able to establish with certainty the current status (alive or deceased) for many patients on the list. This work is ongoing and may well be updated following the cross-referencing exercise with the HPS database. We also have no readily available information on causes of death, but again efforts will be made to establish this detail. Thus at present we can only determine that of 314 cases known to be HCV positive or likely to have had NANB hepatitis, 88 are known to be no longer alive, and of these 88 liver disease was a major contributor to death in 29 out of the 65 for which we currently have 'cause of death' details.<sup>93</sup>

**3.80** Dr Tait confirmed that for the 65 patients for whom cause of death details were available, the data were provided largely by HPS from the information noted on death certificates, albeit some data may also have been provided by the UKHCDO.<sup>94</sup> To date, Dr Tait and colleagues have not been able to undertake further work on the causes of death of coagulation disorder patients infected with HCV.<sup>95</sup>

<sup>92</sup> The witness 'Laura' was a case of secondary infection – the only case disclosed by the evidence. See Chapter 6, *An Examination of the Effects of Infection with Hepatitis C on the Patients and their Families, Including Treatment*.

<sup>93</sup> *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016], at 0020, paragraph 5

<sup>94</sup> Day 14, Pages 130–131

<sup>95</sup> Dr Tait's response to further questions on statistics, 8 January 2013 [PEN.019.1306]

**3.81** Dr Tait discussed a separate exercise undertaken by the Scottish Haemophilia Directors to document key features relating to HCV infection in patients looked after in the Scottish centres. Dr Tait explained: 'The patients included were predominantly infected in Scotland but include small numbers of HCV-infected patients who had moved to Scotland and were being cared for in a Scottish centre.'<sup>96</sup> The results of that exercise were set out in an Abstract which noted that, overall, 248 of 291 patients infected with Hepatitis C (85%) were still alive as at summer 2007. Death had occurred in 11 out of 33 patients (33%) who were co-infected with HIV, against 32 out of 260 patients (12%) who were infected with Hepatitis C only.<sup>97</sup>

**3.82** The updated statistics report provided by the UKHCDO included data on the cause of death of the 193 patients who had been exposed to Hepatitis C as a result of their treatment with factor concentrate and who, as at 2011, were known to be dead. The report explained:

The number and causes of death data are derived from reports from centres and reports from the Office of National Statistics. We provide them with details of all (25,000+) patients registered with the database and they flag them up when they die and send us death certification data.<sup>98</sup>

**3.83** The UKHCDO advised that of the 193 patients exposed to Hepatitis C as a result of their treatment with factor concentrate who were known to have died as at 2011, 21 patients had a liver-related cause of death.<sup>99</sup>

**3.84** Professor Goldberg gave evidence that, as at December 2009, of the 351 patients with blood disorders recorded by HPS as having contracted Hepatitis C as a result of treatment with a blood factor, 78 patients were known to have died.<sup>100</sup> Of these 78 individuals, 15 had a primary liver-related cause of death recorded on their death certificate and 15 had a secondary liver-related cause of death recorded. Professor Goldberg added the caveat that 'it is not possible to conclude, from this information alone, if Hepatitis C materially contributed to death in these instances'.<sup>101</sup> As will be seen in the discussion of deaths among transfusion patients at paragraph 3.260, Professor Goldberg did not regard death certificates as a reliable means of identifying those whose cause of death related to infection with Hepatitis C.

**3.85** As can be seen from the discussion above, it has not been possible to arrive at an exact number of deaths resulting from HCV infection among patients with bleeding disorders. The current status of some patients is unknown, and even where a patient is known to have died, determining the role of HCV from the information on the death certificate involves some guesswork. The following figures emerged from the various investigations reported to the Inquiry:

<sup>96</sup> *Methodology for collation of Scottish HCV & NANB data for Penrose Inquiry*, Dr Campbell Tait, 23 February 2011 [PEN.013.0016] at 0020, *Scottish Haemophilia Directors 2007 review of HCV and its treatment in Scotland*. This list of patients is different to the list of 459 patients discussed above, who the Scottish Haemophilia Directors considered may have been infected with HCV as a result of their treatment in Scotland.

<sup>97</sup> Khan *et al* 'Outcomes of hepatitis C infection in a large haemophilia population' [PEN.013.0008].

<sup>98</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012, page 55 [PEN.019.0927] at 0987

<sup>99</sup> *Ibid*, table 9, pages 54–55 [PEN.019.0927] at 0986–7

<sup>100</sup> Professor Goldberg's statement on statistics relating to haemophilia patients infected with HCV, dated 1 February 2011 [PEN.001.0206], question 5 and page 0208. While 273 individuals were 'not known to have died', that does not mean that any of these individuals had not in fact died. Some of these individuals may have died but their deaths were not notified to HPS.

<sup>101</sup> Professor Goldberg's statement on statistics relating to haemophilia patients infected with HCV [PEN.001.0206], question 5

Source	Population in study	Deaths with liver-related cause
Scottish Haemophilia Directors (reported by Dr Tait)	314 cases known to be HCV +ve or likely to have NANBH	29
UKHCDO	193 patients known to be HCV +ve and known to have died at 2011	21
HPS (reported by Professor Goldberg)	351 cases recorded as HCV +ve	30

### Patients exposed to risk of transmission of Hepatitis C as a result of blood transfusion

**3.86** The second group to be considered is referred to in paragraph 3.2, item ii, and consists of patients who were exposed to infection with Hepatitis C through transfusion with blood or blood components.

**3.87** There are several particular issues relating to transmission of HCV by transfusion around:

- the number of patients exposed to risk of infection;
- the number of individuals infected with HCV;
- the number of those infected who have been seriously affected by disease;
- the mortality from liver disease among those infected; and
- the numbers of infected individuals who might still be alive.

**3.88** Finding the answers to some of the questions that arise remains problematic. For example, the Inquiry has gathered evidence of the adverse consequence of infection for specific individuals, reflected in the narrative of patients' experiences, which demonstrates that in some cases the progression of disease has been associated with severe morbidity. These patients essentially make up a large but self-selected group of individuals prepared to provide evidence to the Inquiry. It cannot be assumed that they are representative of a wider population of patients, and inferences about total numbers affected to a similar extent cannot be valid. At most a general inference that significant numbers of patients are probably severely affected would be justified.

**3.89** It is not known how many patients in Scotland contracted Hepatitis C as a result of blood transfusion, following the increasing use of transfusion between the end of the Second World War and the introduction of the screening of donors for Hepatitis C in September 1991. There are several reasons for that. The size of the total population at risk is not known – that is the numbers of patients receiving transfusions of whole blood, or blood components which might have transmitted the virus, in the course of surgical or medical treatment, over the period when there was in fact a risk of transmission of infection. That period started before the reference period of the Inquiry. Material risk was probably low in the early 1970s. It grew thereafter with the increased prevalence of HCV infection in the general population, and by inference to some extent in the donor population. That increase can be estimated statistically, but is essentially unquantifiable. This major building block in any statistical analysis of the extent of HCV infection in transfusion recipients is at best incomplete.

**3.90** Inevitably, much of the evidence received has related to retrospective studies. In general terms, regardless of the infection concerned, the length of time over which the interval of retrospection extends may be a factor affecting the availability and reliability of the data available for study. There may be insufficient biological material (usually stored serum) from possibly infected individuals available to researchers for study. The virulence of the agent affects the reliability of studies. Very serious, often fatal, diseases may have left few survivors by the time the retrospective analysis is attempted. The age and co-morbidity of the infected individuals at the time of transmission also affects the population available for study. The longer the time that has elapsed since the putative transmission event, the more likely it is that the recipient has died. The cause of death may be related to the infection transmitted, or a cause other than the infection itself.<sup>102</sup> Older individuals affected by other unconnected but serious illnesses, may have died before the retrospective study is carried out, unaffected by the infection transmitted or where the contribution of that infection had not been identified.

**3.91** The infection may be distributed within a very large, heterogeneous, population. It may be impractical to test individuals from all cohorts within the population and extrapolation from one particular group to the population as a whole may lead to serious inaccuracies. Similarly, attempts to identify the incidence and prevalence of an infection from symptoms, may be vitiated when only a small proportion of those infected display recognisable symptoms within weeks, months or even years of acquiring the infection. The study of Hepatitis C in NHS patients provides a particular example of these difficulties.

**3.92** In contrast to patients with coagulation defects, most of whom benefit from regular monitoring and treatment as part of the management of their primary disease, the follow-up of patients receiving blood transfusion in the course of medical or surgical procedures has been less structured and less comprehensive. In addition, the vast majority of patients who have contracted Hepatitis C through transfusion are likely to have done so at a time before the virus was identified. By the time tests became available to diagnose the disease, many of those patients will have died untested for the virus (mostly as a result of age-related conditions or as a result of the condition which necessitated the transfusion). Of those patients who contracted Hepatitis C through transfusion and who were still alive when diagnostic tests became available, many have not been tested for Hepatitis C. Most of these patients will have been unaware that they may have been infected with the virus at the time of transfusion, since only a small minority of patients experience significant symptoms when first infected. For the majority of patients who are infected, symptoms readily related to the infection are unlikely to appear until decades later.<sup>103</sup> On the other hand, a proportion of those exposed to the virus either do not become infected or, if infected, spontaneously clear the virus and in either case would test negative for the virus. They would not go on to develop any Hepatitis C disease manifestations.

**3.93** Of those patients who develop symptoms and who test positive for Hepatitis C, a transfusion (possibly many years ago) may not be identified by the patient or the patient's clinician as the likely source of infection. In those cases where transfusion is identified as a possible route of transmission, matters may be complicated by the presence of other

---

<sup>102</sup> Dr Gillon – Day 6, page 22

<sup>103</sup> Professor Goldberg and Dr Schnier stated, 'HCV infection, in over 95% of instances, is a silent event, with the consequences of long standing infection only becoming apparent decades after its acquisition'. *Estimation of the Number of Individuals Infected as a Consequence of Blood Transfusion in Scotland 1970–1991* – Goldberg and Schnier [PEN.018.1561], paragraph 4.1.

possible routes of transmission which cannot be excluded, such as intravenous drug use, which is by far the most common route of transmission overall in Scotland and in the rest of the UK.

**3.94** Despite these considerable difficulties, the Inquiry has attempted to investigate the number of patients who may have contracted HCV as a result of blood transfusion in Scotland. Several sources of evidence have been drawn to the attention of the Inquiry. There were radical changes in reporting structures in 1995 and 1996 which complicate discussion of the sources and of the data contributed. It is appropriate, however, to note that the problem facing the Inquiry is not new: look-back studies were initiated to find and inform those who had been infected, out of a sense of responsibility for their welfare. The investigation of the numbers affected arose incidentally in that context, and it is to the conduct and outcome of those studies that it is necessary first to turn.

### *The look-back studies*

**3.95** Targeted HCV look-back studies, first in the Edinburgh and south east region of the SNBTS and later throughout the UK, are discussed generally in Chapter 35, *An Investigation into the Steps Taken to Identify the Individuals who were Infected (Look-back)*. In 'targeted look-back' the donation histories of individuals found to be infected when screened for a specific pathogen are followed with a view to tracing possible recipients of blood, blood components or products prepared from previous donations by those individuals, in order to ascertain whether any of the recipients may have contracted the virus. For the purposes of this chapter, the outcome of the national HCV look-back discussed in Chapter 35 at paragraphs 35.182 to 35.193 is relevant.

**3.96** The national look-back was initiated in 1995 and ran until 1998, using data available following the introduction of anti-HCV screening in September 1991. Prospective donors who tested positive comprised individuals who had not been dissuaded from offering blood by self-exclusion literature, which they may have ignored or not known of, or which they may have thought irrelevant to them. For present purposes, those found to be anti-HCV positive can be assumed to have been apparently healthy individuals. The results of the first few months of testing in England and Scotland, showed anti-HCV prevalence values among the blood donors tested, of 0.066% and 0.088% respectively.

**3.97** In the case of return donors found to be HCV positive, prior donations were traced and, where available, stored samples were tested for infection. The destinations of infected donations were then traced, and those used for clinical purposes identified. The hospitals to which blood or blood components – red cells or platelets, for example – were issued were contacted through formal routes, informed of the facts and asked for details of the status of the individual component. They were asked in particular whether a patient had received it and, if so, whether the recipient patient could be identified.<sup>104</sup>

**3.98** On 31 January 2006 the Health Minister of the Scottish Executive provided the results of the look-back exercise to the Health Committee of the Scottish Parliament.<sup>105</sup> The results, taken from the final report of the look-back exercise, are summarised in Tables 3.8 and 3.9.

<sup>104</sup> Dr Gillon – Day 6, pages 75–76

<sup>105</sup> See Letter from National Medical & Scientific Director, SNBTS, to Dr Aileen Keel, Scottish Office, dated 28 April 1998 [SGF.001.2174] and Scottish Hepatitis C Lookback Results – 9 April 1998 [SGH.002.8669]; the note to paragraph 7 of Letters from Minister for Health and Community Care [PEN.002.0801] at 0804; and more generally, paragraphs 9.309 to 9.313 of the Preliminary Report.

**Table 3.8: Results of Scottish Hepatitis C look-back**

Hepatitis C positive donors who had given blood before 1991	360
Donations by those donors	1658
Components prepared from those donations	2026
Of which – Traced	1356
Not traceable	670
Number of recipients identified by hospitals	880
Potentially eligible for counselling and testing	266
Of which – Counselling and tested positive	133
Counselling and tested negative	70
Other – Declined; not appropriate for testing; results not reported back to SNBTS	63
Deceased	536
Not traceable	78

**3.99** The number identified in the Scottish look-back report may have substantially understated the full extent of the problem. Screening and enquiry after the commencement of HCV testing in September 1991 identified infected blood donors who had given donations before 1991. Previous donors who were infected with HCV but did not present again after the introduction of HCV testing in September 1991 could not be identified, nor could their prior infective donations. Among recipients of blood from donors in this category there may have been individuals who developed the clinical manifestations of HCV infection and were treated by the NHS, before or after September 1991. The look-back exercise did not target those individuals.

**3.100** As shown in Table 3.8, in total the group identified had given 1658 donations which were available for clinical use. The data recorded showed that an average of 1.2 components were prepared from each donation. The destinations of 1356 of the total of 2026 components were traced. The destinations of the remaining 670 were not traced, and therefore whether they were applied in treating patients, or discarded, could not be determined. Only 880 recipients of the 1356 components traced were identified. Five hundred and thirty-six of these recipients (60%) were already dead by 1995 and could not, therefore, be tested.<sup>106</sup> Of the remaining recipients, some were not traceable, some were unwilling to be tested, some patients were very elderly, very ill or had a low life expectancy, or were incapable of consenting to testing, and some results were not returned for recording. In the end, in Scotland, 133 individuals were counselled and tested positive, 70 were counselled and tested negative, and the remainder fell out of the scope of the project. Only 203 of the 880 recipients contributed relevant data.<sup>107</sup>

**3.101** Data recovered and held by the HPA on the National Hepatitis C Register in respect of 103 of these patients show known dates of exposure as set out in Table 3.9.<sup>108</sup>

<sup>106</sup> Dr Gillon gave evidence that various studies had been carried out in different parts of the world which showed that in the late 1980s and early 1990s, about one half of patients who received a transfusion died within a few years, often as a result of the underlying condition which necessitated a transfusion, or through old age: Day 6, page 29

<sup>107</sup> Dr Gillon – Day 6, pages 26–30

<sup>108</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HCV [PEN.001.0043] pages 3–4

**Table 3.9: Known dates of exposure to HCV**

1977	1
1983	3
1984	4
1985	8
1986	11
1987	9
1988	14
1989	19
1990	15
1991	19
Total	103

**3.102** The range of values over the period probably reflects the reality that for earlier periods more patients would have died or have disappeared without having been identified.<sup>109</sup> Furthermore, it is likely that the proportion of donors found to be HCV positive in 1991 who would also have been donors in the early 1980s, is smaller than in the later years of the decade. Forty nine of those 103 patients were known to be alive at January 2011. In Dr John Gillon's view, Hepatitis C caused or materially contributed to the deaths of eight of the 54 patients known to have died. In one case no cause of death is known.<sup>110</sup> Of the 53 for whom death certificates were available, Hepatitis C was recorded on 14 only, though all 53 were known to have been infected.<sup>111</sup> Dr Gillon explained:

I should also add that these data are so far not analysed by HPA and haven't been published. So this was kindly made available to us by Dr Helen Harris for the purposes of the Inquiry. The interpretation which I have given is a personal interpretation, and may not reflect what they finally decide when they analyse these things formally through HPA and publish the data ....

I really categorised people into those who had clear evidence that their final demise was fairly directly attributable to hepatic disease. In other words they have liver failure or a complication such as sepsis, or they had hepatocellular carcinoma. Again, there may be a primary cause of death such as bronchial pneumonia, but hepatocellular carcinoma ... that is clearly attributable to the Hepatitis C.

So my reading is that eight of these 53 had a final illness where Hepatitis C was the significant factor.

....

I think that by and large at this sort of length of follow-up, which is 20 years plus now, that's broadly in line with what's in the published literature.<sup>112</sup>

<sup>109</sup> Dr Gillon – Day 6, page 49

<sup>111</sup> Dr Gillon – Day 6, pages 54–55

<sup>112</sup> Ibid, pages 56–58

**3.103** In response to a request by the Inquiry, the SNBTS produced a paper on look-back<sup>113</sup> which sought to explain the relative ineffectiveness of the procedure in relation to HCV. The paper highlighted:

- In contrast to HIV, HCV was present in the population for several decades before a test was implemented;
- HCV typically remained silent following infection in most individuals for many years. HIV may progress rapidly;
- the epidemiology of HCV infection was less well understood than that of HIV, and measures to exclude at-risk donors in the period before development of a test were less effective, though exclusion measures related to HIV infection presumably reduced the numbers of donors with HCV;
- the greater the period elapsed between transfusion and the look-back exercise, the more likely it is that the patient will have died from a cause other than Hepatitis C;
- the increasing use of component therapy put more recipients at risk from a single donation;
- blood bank and hospital records were seldom available from the pre-computer era, and it was almost impossible to trace the fate of donations from before the early 1980s. After the early 1980s many blood banks relied on paper records which could not be searched systematically. It was therefore frequently impossible to establish whether, or to whom, a blood component was transfused; and
- the highly efficient patient tracking systems available today are a relatively recent development.<sup>114</sup>

**3.104** In oral evidence, Dr Gillon expanded on the difficulties with the Hepatitis C look-back exercise.<sup>115</sup>

- Early donor card records were not searchable.<sup>116</sup>
- It was not possible for the SNBTS to identify all prior donations by an infected donor.
- It was not until 1983 or 1985 (depending on the region involved) that a computer system was in place by which each donation could be linked to each donor and, importantly, to each recipient.
- Even where previous donations by an infected donor could be identified, there were difficulties in tracing the recipients of each donation.
- Different transfusion centres and hospitals had different record keeping systems.
- There were difficulties in cross-referencing donation numbers with recipients and vice versa.
- Medical records were lost or destroyed.
- Over time, recipients may have married (and changed their surname) or moved address.

<sup>113</sup> SNBTS – LOOKBACK – *Procedures to identify, trace and offer counselling and testing to patients who received blood components from donors subsequently found to be positive in tests for HIV and HCV* [PEN.017.2220]

<sup>114</sup> Ibid [PEN.017.2220] at 2229

<sup>115</sup> Dr Gillon – Day 6, pages 17–26

<sup>116</sup> Ibid pages 23–24

While the look-back exercise was undoubtedly worthwhile, in Dr Gillon's view, as a means of trying to identify, counsel, test and treat those patients at risk of having contracted Hepatitis C as a result of blood transfusion, it was not a reliable guide to the number of patients likely to have become infected with Hepatitis C through transfusion.

**3.105** Dr Gillon's evidence is accepted. The HCV look-back exercise cannot be relied on as providing an accurate measure of the number of NHS patients exposed to the risk of transfusion-transmitted Hepatitis C virus. Nor does it provide, of itself, a basis for estimating total exposure.

### SNBTS donor data: reporting of transfusion-transmitted infection

**3.106** During the reference period, clinicians were encouraged to report to the blood transfusion service any adverse reactions arising from the transfusion of blood and blood products, including the transmission of infection.<sup>117</sup> However, as previously discussed at paragraph 3.11, there was no effective legal obligation on clinicians to report, nor was there any legal obligation on the transfusion service to report to the Secretary of State or any other central authority, any adverse reactions of which they were aware. It is unlikely that surgeons or other clinicians who were not in a professional relationship with the SNBTS would have read the relevant guidance.<sup>118</sup>

**3.107** A Scotland-wide Hepatitis C diagnosis database, now maintained by HPS, was set up in 1996. The SNBTS and HPS now share basic data on HCV infection. The data are held by the National Microbiology Reference Unit for HPS.<sup>119</sup>

**3.108** The UK transfusion services set up a voluntary informal reporting system in 1996, the Serious Hazards of Transmission (SHOT) system, under which a central body collects and analyses anonymised information on adverse events and reactions in blood transfusion, from all healthcare organisations involved in the transfusion of blood and blood components in the UK and makes recommendations to improve patients' safety.<sup>120</sup> Since then Dr Brian Dow has collated all look-back cases and reports from Scotland and forwarded them to SHOT, providing a database from 1998.<sup>121</sup>

### HPS Hepatitis C Diagnosis Database

**3.109** Anonymised data acquired from Hepatitis C testing laboratories in Scotland is recorded by HPS in the Hepatitis C Diagnosis Database.<sup>122</sup> The primary objectives of the database are (1) to determine the total number of persons diagnosed with HCV infection in Scotland (from whatever source), by reference to year, NHS board, age, gender, risk group and referral source and (2) to monitor trends in diagnosed HCV infection in the Scottish population.<sup>123</sup>

**3.110** Professor Goldberg explained that virology laboratories (in hospitals throughout Scotland) hold information obtained from the Hepatitis C test request form that accompanies a blood sample to the laboratory.<sup>124</sup> Unlike the test request form for HIV,

<sup>117</sup> Recommendations to that effect were contained in various versions of *Notes on Transfusion*. (See for example the 1974 edition [DHF.001.2039] at 2062 and the 1984 edition [DHF.003.0394] at 0413.)

<sup>118</sup> Dr Gillon – Day 6, page 11

<sup>119</sup> Infection Surveillance Report No 11 – 1998–2009 [PEN.001.0053]

<sup>120</sup> Dr Gillon – Day 6, page 34; [www.shotuk.org](http://www.shotuk.org)

<sup>121</sup> *Ibid* page 34

<sup>122</sup> Professor Goldberg – Day 6, page 99

<sup>123</sup> See the HPS website: <http://www.hps.scot.nhs.uk/surveillance/SystemsDetail.aspx?id=33>

<sup>124</sup> Professor Goldberg – Day 6, pages 99–100

there is no standardised Hepatitis C test request form for use throughout Scotland.<sup>125</sup> All forms contain a space for 'additional information' or 'clinical information'. It is by interrogating the test request forms sent to the laboratory that HPS is able to access the information they need for their health surveillance and epidemiological purposes.<sup>126</sup> In his written statement Professor Goldberg said that: 'Hepatitis C information available to HPS ... is not as comprehensive or accurate' as in the case of HIV, due to the use of forms of varying design.<sup>127</sup> It is apparent that there are two deficiencies in the existing arrangements: the lack of consistency in form design and lack of consistency in returning relevant information. Professor Goldberg said that 'sometimes' clinicians provide the laboratory with relevant information in the space for 'additional information' or 'clinical information'.

**3.111** HPS took over data collection from the SNBTS, and the numbers generated by the database are discussed below at paragraphs 3.131–3.139.

### *The numerical evidence: known or recorded cases of transfusion-transmitted HCV*

#### **SNBTS donor data**

**3.112** In the period between 1 September 1991 and 31 December 2009, for which detailed data are available, the SNBTS conducted anti-HCV testing on 546,843 donations from new donors and 4,663,441 donations from repeat donors.<sup>128</sup> It was found that 450 new donors and 417 repeat donors were infected with HCV (that is to say were anti-HCV positive), a total of 867. Though the aggregate numbers were found to be similar, the prevalence rates differed widely. On average over the period the rate of positive donations from repeat donors was 8.94 per 100,000. The rate for new donors was 82.29 per 100,000. The rate overall was 16.64 positive donations per 100,000. The numerical distribution of infected donations over the period is reflected in Figure 3.3. The relative rates per 100,000 donations are shown in Figure 3.4.

**3.113** The data for 1991 are not comparable with the data for the rest of the period, since four months only are reflected in the numbers. For the whole of 1991, SNBTS National Statistics records 332,731 donations (approximately three times the total for the part year). The total for 1992 was 332,825. For the full years from 1992 onwards, a downward trend in positive results has been apparent. It is highly likely that a proportion of the return donors found to be anti-HCV positive in 1992 would have tested positive in the first eight months of 1991. Many donate annually. It is also likely that some donors in that eight-month period who did not return in 1992 would have tested positive. While it might be speculated that the result would be to shift the peak of infected donations back one year, it is impossible to say what the peak values would have been. Individuals' donation patterns vary widely, though the return donor population as a whole is reasonably stable. The trend is reliable only from 1992 onwards.<sup>129</sup>

**Figure 3.3: HCV-infected blood donations: Scotland**

**Figure 3.4: HCV-infected blood donations: Scotland: Rate per 100,000**

**3.114** As would be expected, in the case of return donors, the numerical trend reflects the relatively high initial effectiveness of a new screening test on a largely stable donor population. Dr Gillon identified two further possible contributory factors to the trend: a change in population prevalence of infection, and better donor selection.<sup>130</sup> Of the total of 867 HCV-positive blood donors, 59 (6.8%) stated that blood transfusion was the only risk factor for exposure to infection.<sup>131</sup> That number might include individuals who were transfused outside Scotland. Their cases have not been investigated individually.<sup>132</sup> Initial enquiries known to Dr Gillon established a date of transfusion in nine of 59 cases.

**3.115** The reliability of these reports of an association with transfusion is open to question and it is unclear what inferences can be drawn from the information generated. The following factors demonstrate this lack of clarity:

- The 59 individuals were people who, on receiving counselling, indicated that they thought they had received a blood transfusion in circumstances that suggested that the transfusion might be responsible for their infection. There was no objective verification of their statements.
- The information depended entirely upon reporting by the individual.<sup>133</sup>
- The reporting may have understated their experience of transfusion, as in the case of patients who had forgotten that it had happened, or who may have been transfused under anaesthetic, or who may not have understood the procedure carried out to be a transfusion.
- A clinician responsible for an injection of platelets might not always have informed the patient that he or she had been transfused. For example, in one study in Italy of patients who had well-documented transfusion-transmitted HCV infection, none of the patients knew they had been transfused.<sup>134</sup>
- The responsibility of transfusion may have been overstated by patients who concealed, innocently or otherwise, previous conduct exposing them to risk, such as intravenous drug use, body piercing or tattoos.<sup>135</sup>
- The process will not have identified individuals who were transfused in Scotland but diagnosed as infected in England or Wales or abroad.<sup>136</sup>

**3.116** The differences in prevalence values between return and new donors are significant. The relatively high, and in percentage terms sustained, levels of HCV-positive donations from new donors supports the view that donor demographics and donor selection practices contributed to a relatively low prevalence of HCV-positivity among the established donor population as compared to the general population (represented by the new donors). On the other hand, the impact on total prevalence of HCV-positive donations was low because throughout the period the pattern was dominated by donations from return donors.

<sup>136</sup> *Ibid* page 74

### Patients reported to SNBTS by clinicians as possible cases of transfusion-transmitted (TT) HCV

**3.117** The next group of patients identified by the SNBTS comprised individuals reported to the SNBTS by clinicians, for the most part hepatologists and gastroenterologists, who had treated a patient infected with Hepatitis C where the information available suggested that the likely mode of infection had been transfusion. These cases were investigated individually. It was not always possible to establish a diagnosis of transfusion-transmitted Hepatitis C with certainty. Archives of frozen plasma or serum samples mostly dated back only as far as 1986 and it was often not possible to trace the implicated donors for testing.<sup>137</sup>

**3.118** This exercise was carried out by SNBTS retrospectively to attempt to answer the Inquiry's questions about the incidence of transfusion-transmitted HCV infection, and was dependent on finding and researching individual patients' records in transfusion centres.<sup>138</sup> After that it became a question of judgement. Dr Gillon said:

[T]he information is open to interpretation. It can be difficult to know whether to say, "Well, we accept this as a case of transfusion transmission. This one probably is but we really don't have enough documentary evidence to say with certainty".

On a number of occasions we can rule it out. We can say the blood that this person received was tested, all the donations were negative, all of the donors have come back and tested negative subsequently. We can be confident that transfusion did not transmit that infection. There are some cases where you can feel that the information that we have is a bit skimpy and therefore you would hesitate to say that this is likely to be a transfusion transmission. But we know there are other ways of picking up transmissible viruses in hospital environments, as we will see in some of the data from the renal units, for instance. Therefore, unless we can identify a donor and establish that link with certainty, there is always a bit of interpretation that's necessary here. I have tried to be inclusive here. In other words, not to wish to minimise the figures in any way, but there is this caveat that, we can never be certain unless we make the link.<sup>139</sup>

**3.119** After investigation of the reports, the numbers accepted as 'known' cases of transfusion-transmitted HCV, as detected by these means, were:

- Glasgow and west of Scotland 6
- Edinburgh and east of Scotland 15
- Dundee (east of Scotland) 4
- Aberdeen (north east Scotland) 3
- Inverness (north of Scotland) 0

<sup>137</sup> Ibid page 32

<sup>138</sup> Ibid pages 33–34

<sup>139</sup> Ibid pages 34–35

**3.120** It is apparent that the numbers for the two major centres are not proportionate to the respective populations of the regions. Dr Gillon thought that the total number of 28 underestimated by a considerable margin the residual number of undetected TT HCV cases.<sup>140</sup> Historically, the SNBTS tended to see reports from haematologists, for instance, who were dealing regularly with patients requiring multiple transfusions. There was fairly close and constant interaction with them. Similarly, in units which used a lot of blood, like cardiac surgery, renal units and other units with whom the SNBTS had clinical links, clinicians were more alert to the possibility of transfusion-transmission than a surgeon at a district general hospital who was much less likely to think of the possibility.<sup>141</sup>

**3.121** Actual dates of transmission have not been established in these cases. For all but one patient, probable dates lie between 1979 and March 1991. One patient received multiple transfusions between 1970 and 1983 and identification of the infective donation was impossible.<sup>142</sup>

**3.122** As regards this group of known infected patients, one cannot equate the number of cases of transfusion-transmitted Hepatitis C reported by clinicians, with the prevalence of transmission. As already noted, only about 20% of individuals who contract Hepatitis C will experience an initial acute period of illness (eg jaundice) and may be aware that they have contracted a disease. The corollary is that the vast majority of patients who contract Hepatitis C, and their clinicians, will be unaware at the time that infection with the virus has occurred. While a patient may, many years or decades later, develop symptoms and be tested for Hepatitis C, only in some cases will the patient and treating clinician attribute that to a prior transfusion and only in a minority of these cases will this be reported to the SNBTS. Many more cases will remain undetected or unreported for a number of reasons, including the death of many patients before symptoms from hepatitis developed, the patient or clinician not attributing infection to a transfusion occurring many years previously or the clinician not reporting the matter to the SNBTS. While 28 cases in this category were accepted by the SNBTS as being 'known' cases of infection, Dr Gillon stated: 'I think there is no doubt that a total of 28 is way off what is the reservoir of such cases in the population. We don't know by how much of course.'<sup>143</sup>

### *Summary of SNBTS known or recorded cases*

**3.123** On SNBTS evidence, the total number of patients infected by transfusion and identified in these various exercises was therefore 220 (133 patients identified by the look-back exercise plus 59 donors who were thought to have been infected by a prior transfusion, plus 28 patients reported to the SNBTS by clinicians). Dr Gillon thought that the total numbers identified by his studies were probably minimum numbers for infections in Scotland.<sup>144</sup>

**3.124** Dr Gillon acknowledged that there was a theoretical possibility of overlap among the three groups of patients, but it was unlikely to have occurred. He knew of no HCV positive donor in the SNBTS group who was subsequently identified as a patient in the targeted look-back. The documentation and procedures used in the targeted look-back differed from the other groups. Patients from the third group were individually researched.

<sup>140</sup> Dr Gillon's further statement on statistics [PEN.013.1557] at 1558 and Day 6, Page 40

<sup>141</sup> Dr Gillon – Day 6, pages 41–42

<sup>142</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HCV [PEN.001.0043] at 0046

<sup>143</sup> Dr Gillon – Day 6, page 40

<sup>144</sup> Ibid page 77

There was a risk that a patient identified within the third group might subsequently have been identified by the targeted look-back without a connection having been made. The anonymising of data recorded by the HPA, and the numbers of cases recorded by the HPA, made it impossible to rule out the possibility, but the risk was unlikely and the numerical impact of such an event would be small.<sup>145</sup>

**3.125** It would not be appropriate to conclude on the basis of the SNBTS donor data that only 59 HCV positive blood donors had been infected by blood transfusion. In particular, donors who stopped donating prior to the introduction of Hepatitis C screening in September 1991 would not be included. Similarly, neither the 133 patients identified by the look-back exercise nor the 28 reported by clinicians provides a reliable guide to the total who may have become infected. Nor is it possible to develop from these numbers an estimate of the total number of patients who may have been infected by transfusion. None of the individual figures provides a basis for inference of that total. Individually, the cohorts are too small to support a more general conclusion. In total they represent an aggregate only of small numbers in specific groups: they are not random samples from which a more general picture can be inferred.

### Renal and other units

**3.126** Following the development of tests for HCV antibodies, certain patients were screened for HCV on a regular basis by local virology laboratories. The patient groups included people with haemophilia, bone-marrow transplant recipients, and renal dialysis patients. Some positive data were derived from this work. Transfusion transmitted HCV was confirmed from the patients' treatment records.

**3.127** Renal dialysis patients considered to be known positives for TT HCV were identified separately. The renal unit in the west of Scotland had monitored the patients because of the well-known risk of hepatitis transmission in renal units.<sup>146</sup> Initial interest had been in Hepatitis B, which had a high prevalence in patients on chronic dialysis, for reasons that were poorly understood at the time. In addition, patients with chronic renal failure are usually anaemic, and those with severe anaemia as part of their condition require regular transfusions. Therefore, many of them would have had numerous transfusions and most of those would probably have predated the time when the sample archive was started in the west of Scotland in 1986. The patients in this group were reported by the renal units in the west of Scotland as possibly having been infected with transfusion-transmitted Hepatitis C when they started routine testing for HCV antibody.<sup>147</sup> These patients may have been infected through blood transfusion, but the large number of transfusions administered, and substantial risk of nosocomial infection from other sources, made it impossible to say if and when they had been infected by transfusion-transmission.<sup>148</sup>

**3.128** In addition, a very small number of patients had, prior to the national look-back exercise, been identified by the West of Scotland Blood Transfusion Service as HCV positive. These patients numbered 18 and were primarily people with leukaemia who had received multiple transfusions over many years, leading to bone marrow transplantation. The dates of the transfusions were between 1982 and April 1991; identification of the infective donations was considered impossible because of the number of transfusions involved.

<sup>145</sup> Dr Gillon's further statement on statistics [PEN.013.1557] at 1558 and Day 6, page 40

<sup>146</sup> Dr Gillon – Day 6, pages 42–43

<sup>147</sup> Ibid pages 43–44 and Dr Gillon's further statement on statistics [PEN.013.1557] at 1559

<sup>148</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HCV [PEN.001.0043] and Day 6, Pages 44–45

**3.129** Dr Gillon said:

In such a case, really the only way you can find if there is a donor who transmitted would be to have archive samples which you can go back and test. We have certainly in Edinburgh done occasional look-backs where we have tested between 100 and 200 samples, which is a very big exercise. Occasionally it does provide results. But some of these patients will have had hundreds of individual units of transfusion and many of them will have had these transfusions before the archive samples started, which would make it impossible.<sup>149</sup>

**Conclusion on the SNBTS data**

**3.130** On the basis of these SNBTS data, it is possible to conclude only that 238 known patients (220 + 18) were infected by transfusion-transmitted Hepatitis C, but that they are very likely to be parts only of larger cohorts of patients.

**Health Protection Scotland data**

**3.131** As noted above, HPS took over data collection from SNBTS. The changes introduced by the Public Health etc. (Scotland) Act 2008 with effect from 1 January 2010, appear to give regulatory effect to the practice of HPS in obtaining information directly from HCV diagnostic laboratories. Professor Goldberg said, however, that HPS 'got better information by going direct to the hepatitis testing laboratories' on a voluntary basis, and that the 'voluntary approach' enabled HPS 'to get the information that we actually needed'.<sup>150</sup>

**3.132** The SNBTS data were passed to HPS' National Microbiology Reference Unit.<sup>151</sup> The remit of HPS is primarily related to preventing future infection and disease. As noted above, HPS established its Hepatitis C diagnostic database in 1996. By then blood transfusion and blood products were not serious issues in the context of preventing further transmission of HCV (since by that time blood donations were screened for HCV and blood products were subjected to processes that were effective in inactivating any Hepatitis C virus in the product). Currently 1000 to 1500 people are thought to become infected with Hepatitis C in Scotland every year, and behaviour exposing people to risk is the focus of much of the energies of HPS, but this does not relate to blood transfusion.<sup>152</sup>

**3.133** As already noted at paragraph 3.20, information is acquired from Hepatitis C testing laboratories in Scotland. The various request forms document demographic information and identifying information. In deriving the information they need for surveillance and epidemiological purposes, HPS then includes other pieces of information that are obtained through surveys of various population groups and also clinical information obtained through a national clinical database.<sup>153</sup>

**3.134** The data available to HPS and recorded in the HCV database indicated that 304 individuals may have been infected with HCV by blood transfusion. In these cases, transfusion could only be regarded as a possible and not a definite or confirmed route of acquisition.<sup>154</sup> In arriving at the figure of 304 cases, 51 individuals were excluded because

<sup>149</sup> Day 6, pages 46–47

<sup>150</sup> Professor Goldberg – Day 6, pages 103–104

<sup>151</sup> Dr Gillon – Day 6, page 15

<sup>152</sup> Professor Goldberg – Day 6, pages 111–112

<sup>153</sup> Ibid pages 99–100

<sup>154</sup> Ibid pages 98–99

they recorded intravenous drug use as well as having received blood transfusions. Between 80% and 90% of drug injectors at most centres were infected with Hepatitis C and it is thought that the 51 individuals were much more likely to have been infected by that means than by blood transfusion.<sup>155</sup> A further 49 had also been previously excluded because the information provided indicated very strongly that they received their infected transfusions abroad.<sup>156</sup> That did not conclusively prove that the remaining 304 were transfused in Scotland, only that they might have been transfused in this country.<sup>157</sup>

**3.135** The data are acceptable as accurate reflections of the information available, given the criteria applied, but they do not define the scope of the problem of transfusion-transmitted HCV infection. Professor Goldberg said:

I think that, because there is so much uncertainty about these cases ... what we are doing here is just taking some information that has been recorded on a request form. We did not seek additional information. We didn't clarify whether indeed the information provided was accurate. So that was why the word "possible" was provided here.

If I had to put money on it, I would say that less than 50 per cent of the 304 contracted their HCV through blood transfusion.<sup>158</sup>

**3.136** That was his personal assessment, but he was not sure that there were sufficient data to make a judgement, and his ultimate position was that 'don't know' was probably the correct answer.<sup>159</sup> It is appropriate to accept that view of the position. The identification of 304 individuals as possibly infected by transfusion-transmission already involves a number of assumptions. Breaking the number down further, without a rational basis, seems problematic.

**3.137** However, while acknowledging that the lack of confirmation associated with blood transfusion was a weakness in the system, Professor Goldberg stated that he was 'pretty confident' that the information that Scotland had on Hepatitis C was 'as good as, if not better than, anywhere else in the world'. He added:

I think there are weaknesses in our information base with respect to blood transfusion and blood factor, but in general our information about Hepatitis C is pretty good. If you want to compare our diagnostic information, ie numbers of people known to be infected, with the information available in England, then we are in a far superior position in terms of the completeness of our data and indeed its accuracy.<sup>160</sup>

### *Conclusion on the HPS data*

**3.138** Like the SNBTS data, the HPS data relate to patients who had been identified as HCV positive and for whom it was likely that infection had been transfusion transmitted. The data do not reflect directly the possible or probable level of infection from transfusion in the whole population of patients exposed to risk from infected blood or components.

<sup>155</sup> Ibid pages 143–144

<sup>156</sup> Ibid page 144

<sup>157</sup> Ibid pages 144–145

<sup>158</sup> Ibid page 106

<sup>159</sup> Ibid pages 145–146

<sup>160</sup> Ibid pages 110–111

**3.139** Even if all 304 individuals on the HPS database acquired Hepatitis C as a result of blood transfusion, that is highly unlikely to reflect accurately the number of transfusion-transmitted infections in Scotland, largely for the reasons discussed above. In particular, patients will not appear on the HPS Hepatitis C database if they had died (for example from age-related conditions or from the underlying medical condition which necessitated transfusion) prior to the database being set up in 1996. Nor will those patients who contracted Hepatitis C but have never, or have not yet, presented to their GP for examination or treatment. Nor will those patients who have presented but for whom, for whatever reason, their Hepatitis C infection has not been diagnosed or, if diagnosed, has not been attributed to a prior transfusion.

### *The Skipton Fund*

**3.140** The Skipton Fund was established on 25 March 2004 by the Department of Health, to make *ex gratia* payments to people who were infected with Hepatitis C through treatment with NHS blood or blood products prior to September 1991.<sup>161</sup> Payments are made in two stages, the first on proof of infection and the second on proof of progression to serious liver disease. Those living applicants who qualify for a stage 2 payment qualify also for regular payments thereafter. In 2011 the Caxton Foundation was set up to provide charitable benefits to certain individuals who have received blood, blood products or tissue from the NHS and in consequence have been infected with HCV, and to individuals who have had infection transmitted by such a person (the 'primary beneficiaries') and to the partners, carers, children and dependants of primary beneficiaries living or who died before 29 August 2003.

**3.141** As at 25 February 2011, there had been 636 Scottish applications to the Skipton Fund for stage 1 payments, of which 134 patients had also applied for and received stage 2 payments, as shown in Table 3.10 below.<sup>162</sup>

**Table 3.10: Scottish applications to the Skipton Fund at 25 February 2011**

Patients with:	Stage 1	Stage 2
Haemophilia	210	33
Haemophilia with HIV	21	9
Non-bleeding disorder	405	92
Total	636	134

**3.142** At least 24 of the total of 636 had died by 25 February 2011. Fifteen of the stage 1 payments and 15 of the stage 2 payments went to an estate. At that stage there were 405 non-haemophiliac recipients of blood or blood components in Scotland who had been alive or were survived by qualifying beneficiaries as at August 2003 and who received payments from the Skipton Fund. The figure was unlikely to represent the actual number of patients who contracted HCV as a result of treatment with NHS blood or blood products. A minimum of 12 years, in many cases 20 years or more, will have elapsed between the time of infection and the commencement date of the Fund in 2003. Mr

<sup>161</sup> In setting up the Fund the DoH was acting for and on behalf of the UK health administrations, ie the Secretary of State for Health, the Scottish Ministers, the National Assembly for Wales and the Department of Health, Social Services and Public Safety in Northern Ireland. The Fund criteria previously did not allow payments in respect of those who died before 29 August 2003. In January 2011, it was decided to relax that criterion. In England the relaxation was applicable only if such claims were made on or before 31 March 2011. The three month registration window did not apply in Scotland.

<sup>162</sup> E-mail from Nick Fish, Scheme Administrator, dated 25 February 2011 [PEN.019.1358]

Nick Fish, the Scheme Administrator, provided further information on 1 March 2012.<sup>163</sup> By then Skipton had made 670 stage 1 payments in Scotland (34 more than shown in Table 3.10 above). 162 of the individuals, or their estates, had also received stage 2 payments. It is unlikely that there will have been a material increase in the sizes of the haemophilia groups, given the level of monitoring in their case, and it seems reasonable to proceed on the basis that the additional 34 cases could be added to the post-transfusion group which had increased to 439.

**3.143** The accuracy of the Skipton data depends on the accuracy of the medical certificates submitted and the rigour of the assessment procedure carried out.

**3.144** Professor Goldberg commented on the Skipton Fund survival data, in particular as a basis for back-calculating plausible estimates of the number of individuals who must have been infected in the first place. He noted:

[I] asked the Inquiry for details confirming that the individuals considered eligible for Skipton funding had, indeed, acquired their infections through blood transfusion in Scotland but such information was unavailable. It is my understanding that, for some individuals, such information exists but for others, perhaps the majority, judgements were based 'on the balance of probability'. Balance of probability is insufficient information for us to make a judgement as to how likely an individual was infected as a consequence of a blood transfusion, without having access to additional information.<sup>164</sup>

He and his colleagues therefore considered the Skipton data to be insufficiently robust for their purposes.

**3.145** As discussed above, It is clear that HPS' own data and analyses lack the level of certainty that would enable one to say that the reference cohort of infected individuals had 'indeed' acquired their infections through blood transfusion. The Inquiry cannot avoid expressing a view on the ground that certain facts can only be established on a less demanding test. The question is whether the Skipton data can be used, along with other sources (including HPS' evidence), in arriving at a conclusion about the likely level of transfusion-transmitted HCV infection.

**3.146** The Inquiry has identified one case in which a claim was admitted where there is no evidence that the deceased patient acquired his Hepatitis C infection from blood or blood products. There may be more. One cannot proceed on the view that the Skipton data are unquestionably accurate. The information available indicates that applications are decided by the Fund on a balance of probabilities test and if refused, applicants can appeal to an independent Appeal Panel.<sup>165</sup> It appears reasonable to accept the figure of 405 (or 439, if the assumption in paragraph 3.142 is valid) as sufficiently accurate to be taken into account in an overall assessment of the level of transfusion-transmitted infection.

**3.147** However, as previously discussed at paragraph 3.92, some patients may have cleared the virus, some may have died without infection with Hepatitis C being diagnosed, and some may survive without signs or symptoms of infection having been noted or brought to the attention of those keeping the relevant records. In the case of the Skipton Fund, it

<sup>163</sup> Email from Nick Fish, Scheme Administrator, dated 1 March 2012 [PEN.019.0104]

<sup>164</sup> Letter from Professor Goldberg in response to further queries on statistics from Professor Oliver James [PEN.019.0922]

<sup>165</sup> [www.skiptonfund.org](http://www.skiptonfund.org)

cannot be assumed that every person entitled to make a claim did so. In the result, both the number of those who died while infected, and the number of individuals who remain infected, but who have not been registered by the Skipton Fund, are unknown.

**3.148** That number may be significant, and it will be appropriate to return to the Skipton data to consider whether estimates can be made on the basis of the recorded data.

### *Summary of recorded data*

**3.149** In summary, known or recorded cases of transfusion-transmitted Hepatitis C infection represent a minimum number of patients who were infected with Hepatitis C as a result of transfusion and do not reflect the actual number of patients who are likely to have contracted the disease in that way.

**3.150** A wider exercise was required to ascertain whether the available data could, with appropriate analysis and expert advice, provide answers.

### *Statistical modelling*

**3.151** As is illustrated by the earlier discussion of data for actual cases of transmission of infection, attempts by epidemiologists retrospectively to form views on the incidence and prevalence of an infection may be hampered by many factors. The general problems discussed in paragraphs 3.89–3.93 arise also in the context of statistical modelling.

**3.152** With respect to HCV infection, of the two main groups under consideration in this section, the haemophilia population is much more homogeneous. Patients tend to be much younger at the date of infection than transfusion patients. On the whole, haemophilia patients are much more rigorously followed up. In their case it is far easier to get reasonable, if not perfect, estimates of numbers infected with HCV than in the very much larger and more heterogeneous population of surgical and medical patients who have received transfusions in the course of treatment of their primary condition.

**3.153** In addition to these general difficulties, HCV is not a virulent, rapidly progressing disease resulting in severe early clinical manifestations or death. Infection may be diagnosed only after long periods of time since the putative transmission. The retrospective study of transfusion-transmitted HCV from 1991 onwards has been affected by all of these factors. The unreliability of the data on actual cases of infection, and the difficulty in forming general conclusions on the basis of those data, are not unexpected.

**3.154** For these reasons, in the absence of reliable recorded data, statistical modelling techniques were adopted by experts for calculating the numbers of transfusion patients possibly exposed to risk, and the numbers of patients infected. Statistical modelling inevitably depends on a number of assumptions in developing general inferences from the data collected. Dr Gillon said that it was difficult to find good data about prevalence in the donor population, to which to relate reported data on patients.<sup>166</sup> Projections were qualified by the accuracy or inaccuracy of the data available and of the assumptions used to derive them. Transforming the raw data into acceptable numbers proved difficult. All of these difficulties have been readily recognised by the investigators in the following exercises.

---

<sup>166</sup> Dr Gillon – Day 6, pages 10–11

***Dr Soldan, Public Health Laboratory Service (PHLS)***

**3.155** In 2002 Dr Kate Soldan, an epidemiologist based at the Communicable Disease Surveillance Centre, PHLS, and a large team of collaborators, estimated the number of individuals who might have been infected with HCV through blood components administered in England.<sup>167</sup> Dr Soldan later carried out a similar exercise relating to the position in Scotland. The results of her English research were to be published shortly after she carried out her work in relation to Scotland.<sup>168</sup>

**3.156** Dr Soldan constructed a model of the path followed by blood components (red cells, platelets, fresh frozen plasma and cryoprecipitate), which had been prepared from donations collected by eight blood centres in England, and had been traced, from donation to recipient, during the national Hepatitis C look-back programme. The eight centres handled 80% of all blood components entering the programme in England. The number of components, 9222, handled by these centres provided the base data used. Some components were followed through every stage, from delivery to application, and some fell out of the process. The proportion of the components that remained 'observed' at each successive stage in the development of the model was calculated. It was assumed that components that did not complete the observed path would probably have followed the path of those that did, and so they were re-entered into the model at the point at which they fell out of the process. The probability that components with an unidentified fate would follow the observed route was calculated at each stage and used to predict the probable fate of those re-entered components.

---

<sup>167</sup> Early information on the exercise was given to Dr McClelland: *Estimates of Number of Individuals Who May Have Been Infected With HCV by Blood Components* [SGH.005.7201] and documents appended: *Estimated Number of Individuals Infected by Blood Transfusion in Scotland* [SGH.005.7203] and *The Contribution of Transfusion to HCV Infection in England* [SGH.005.7205]

<sup>168</sup> Soldan *et al*, 'Estimates of the contribution of transfusion to HCV infection in England', *Epidemiology and Infection*, 2002; 129:587–591 [PEN.013.1580].

**3.157** The history of the 9222 components is shown below in Table 3.11.

**Table 3.11: Dr Soldan's observed path data**

Total Components	9222	100%
<i>of which:</i>		
Components not traced	2119	23%
Components traced	7103	77%
Components traced	7103	100%
<i>of which:</i>		
Components transfused (4586/7103)	4586	64.6%
Components transfused	4586	100%
<i>of which:</i>		
Components with no known recipient (154/4586)	154	3.36%
Components with identified recipients (4432/4586)	4432	96.64%
Number of identified recipients	4424	100%
<i>of which:</i>		
Recipients known to have died (2711/4424)	2711	61%
Recipients assumed to be alive (1713/4424)	1713	39%
Recipients assumed to be alive	1713	100%
<i>of which:</i>		
Recipients not tested (651/1713)	651	38%
Recipients tested (1062/1713)	1062	62%
Recipients testing positive for HCV (539/1062)	539	50.75%

**3.158** In addition to the 1062 tested recipients of components, from the 80% of centres which handled the 9222 components, test results were available (through the look-back exercise) for 271 other individuals. These patients had received components from one or other of the centres in England, providing the remaining 20% of blood. 50.75% of that number (the percentage testing positive in the observed path: 539 out of 1062) provided 138 additional positive tests, giving an overall total of 677 positive tests from 1333 recipients tested.<sup>169</sup>

**3.159** Applying the observed probabilities to components that fell off the process prior to recipient testing and were re-entered, added 3373 HCV infections:

- 946 where the fate of the component was not traced.
- 107 known to have been transfused but with no recipient identified.
- 1870 known to have been transfused to recipients who had died by the end of 1995.
- 450 who declined testing.

Of these, 1870 (55%) were known to be dead and another 645 (19%) were expected to have died by the end of 1995.<sup>170</sup>

<sup>169</sup> The basis on which the percentage from the defined path was applied to this separate group of results is not clear.

<sup>170</sup> Soldan *et al*, 'Estimates of the contribution of transfusion to HCV infection in England'. *Epidemiology and Infection*, 2002; 129:587–591 [PEN.013.1580] at 1581–2

**3.160** Dr Soldan next estimated the probable number of infections from donations that did not enter the look-back study. The number of donations collected between 1 January 1980 and 1 September 1991 was 25,864,035. An infectivity rate of 0.066% was assumed on the basis of observed data from the first four months of donor testing after 1 September 1991. At that rate, it was estimated that 17,086 anti-HCV positive donations would have resulted. At 1.6 components per donation (reported to be an observed datum in England), 26,647 components from infected donors resulted arithmetically.<sup>171</sup> That number necessarily included all or some of the components that entered the look-back programme, and an adjustment was made to deduct those. Of the 26,647 components, it was assumed that 9756 entered look-back in the material period and that 16,890 did not. That would have predicted an extra 10,905 transfused recipients (16,890 x 64.5%), of whom 6034 were infected (based on the observation that 55% of look-back components resulted in infection). However, that was thought unreliable. It was estimated that 73% of the 9756 components entering the look-back programme were anti-HCV positive and accordingly the estimated number of additional anti-HCV positive components not entering look-back was adjusted to 19,525 (26,647 – (9756 x 0.73)). On the consistent assumption that 64.5% of the components traced were transfused, that was calculated to equate to 12,606 recipients of whom 75% (9455) would be infected, on the basis that only HCV RNA-PCR positive donors transmitted the infection.<sup>172</sup>

**3.161** The aggregate, 13,505 (4050 + 9455), was the number of recipients of blood components estimated to have been infected in England with HCV during the decade prior to the start of anti-HCV testing. Over 8300 (61%) of these patients were either known or expected to have died by the end of 1995.<sup>173</sup> Dr Soldan and colleagues noted that: 'There were, by necessity, many assumptions and extrapolations used, and the results are not therefore expected to be exact.'<sup>174</sup> They stated:

We may have underestimated or overestimated the infections transmitted from 1 January 1980 to 1 September 1991 by using the prevalence of infection at the start of testing without accounting for selective removal of infected donors during the 1980s, or accumulation of prevalence over time. This uncertainty, and others, prohibited including earlier years. If the prevalence of anti-HCV amongst blood donors during the 1970s was assumed to be the same as at the end of 1991, inclusion of the 1970s data would generate approximately 10,000 extra HCV-infected blood recipients.<sup>175</sup>

**3.162** It has not been possible to verify the assumptions made.

**3.163** Professor Goldberg commented:

[W]hat she has done here is she has got some pretty solid data ... and then she has extrapolated the findings to those components for which she doesn't have solid data, and I think that's a reasonable thing to do.<sup>176</sup>

<sup>171</sup>  $17,086 \times 1.6 = 27,338$ . The difference of 691 appears to be related to the reduction required to exclude the components related to the 271 individuals whose test results were added from outwith the main centres.  $691 / 1.6 = 432$ ; and  $271 \times 1.6 = 434$ .

<sup>172</sup> Soldan *et al*, 'Estimates of the contribution of transfusion to HCV infection in England', *Epidemiology and Infection*, 2002; 129:587–591 [PEN.013.1580] at 1582–3

<sup>176</sup> Professor Goldberg – Day 6, page 127

**3.164** Professor Goldberg’s evidence is discussed further at paragraph 3.176 below. For the purposes of this Report, it is sufficient to proceed on the basis that the statistical method as applied in England, while open to question in some respects, was not fundamentally undermined by Professor Goldberg, and its results were not seriously disputed on the evidence before the Inquiry.

**3.165** As noted below, the results were used by the Department of Health (DoH), apparently without the need to explain adjustments. On the basis of Dr Soldan’s modelling, the number of HCV infections as a result of blood transfusion in England between 1970 and 1991 can therefore be assumed to have been about 23,500.

### *Department of Health*

**3.166** On 10 January 2011 the DoH published a review of the support available to individuals infected with Hepatitis C and/or HIV by NHS-supplied blood transfusions or blood products, and the dependants of those infected. Annex 2 of the review contained an estimate of the number of Hepatitis C-infected individuals in the UK, who were infected over the period 1970–1991. It was estimated that 28,043 individuals had been infected with Hepatitis C as a result of blood transfusion in the UK during that period.<sup>177</sup> The source for that figure was stated to be the 2002 paper by Soldan and others on the numbers infected in England, ‘corrected to UK’.<sup>178</sup>

**3.167** The population data for the United Kingdom over the period between 1971 and 1991, derived from census returns, are set out in Table 3.12.

**Table 3.12: Population of the UK and constituent countries, 1971–91 (thousands)**

	<b>1971</b>	<b>1981</b>	<b>1991</b>
England	46,411.7	46,820.8	47,875.0
Wales	2740.3	2813.5	2873.0
Scotland	5235.6	5180.2	5083.3
Northern Ireland	1540.4	1543.0	1607.3
Total	55,928.0	56,357.5	57,438.7

**3.168** England had 83% of the total infected population consistently over the period, Wales had 5% and Northern Ireland 2.8%. The Scottish percentage fell from 9.36% to 8.95% and then to 8.85%. For present purposes, it is sufficient to treat Northern Ireland as having 3% and Scotland 9% of the total UK population.

**3.169** The period covered by the DoH estimate was approximately twice as long as the primary period discussed by Dr Soldan in detail (1970–91 as against 1980–91). As already noted, in their published paper the Soldan group commented that if the prevalence of anti-HCV donors during the 1970s was assumed to be the same as at the end of 1991, inclusion of the 1970s data would generate approximately 10,000 extra recipients of HCV-infected blood. Dr Soldan’s 2002 paper therefore suggested that there may have

<sup>177</sup> *Review of the support available to individuals infected with Hepatitis C and/or HIV by NHS-supplied blood transfusions or blood products and their dependants* [PEN.017.1968] at 2007

<sup>178</sup> Soldan *et al*, ‘Estimates of the contribution of transfusion to HCV infection in England’, *Epidemiology and Infection*, 2002; 129:587–591 [PEN.013.1580]

been 23,505 HCV infections as a result of blood transfusion in England between 1970 and 1991.<sup>179</sup>

**3.170** If the United Kingdom blood donor population were assumed to have had the same rate of HCV infection on average throughout the period, the DoH total would be allocated as follows: England 23,276; Wales 1402; Scotland 2524; and Northern Ireland 841. The figure for England is a close approximation of Dr Soldan's estimate of 23,500.

**3.171** Without information about the methodology used by the DoH to adjust for the United Kingdom as a whole, it is not necessarily the case that Dr Soldan's conclusions were accepted nor, if adjusted, to what extent. The most one can establish is that Dr Soldan's conclusions were not challenged by DoH.

**3.172** It seems appropriate to assume that other figures would be reasonable approximations of the data available to the DoH, at least as a starting point. However, the mechanisms by which the DoH values were arrived at are not disclosed, and it is not impossible that they were simply the arithmetical result of extrapolating from Soldan on the basis of population data.

#### *Dr Soldan's Scottish estimates*

**3.173** In 2002 Lord Ross' Expert Group<sup>180</sup> asked Dr Soldan to provide an estimate of the number of patients in Scotland likely to have contracted Hepatitis C as a result of transfusion.<sup>181</sup> Dr Soldan's estimate for Scotland followed the same general methodology as she had developed for the English project.<sup>182</sup> The same statistical model was used and she applied some of the same assumptions, for example in relation to the probability of a blood component being transfused. She also factored in the information available from the Scottish HCV look-back exercise and hence the higher prevalence of HCV among blood donors in Scotland in the first six months of HCV screening (0.088%) when compared with the prevalence among blood donors in England for the first four months' period studied there (0.066%).<sup>183</sup> The exercise was customised by using the numbers of components entering the look-back programme resulting in an identified recipient. It identified recipients who had died, recipients who declined testing, and those who were tested and found to be HCV positive. The exercise was completed using Scottish data and the parameters of the English exercise. Dr Soldan's brief report does not refer specifically to the assumed yield of components per donation. The Scottish datum would have been information that would have had to be provided by the SNBTS. Dr McClelland's letter commenting on Dr Soldan's estimate at the time referred only to 'data from the Scottish HCV look-back programme and also the higher prevalence of HCV in the Scottish donor population' as information provided to customise the exercise.

**3.174** The detailed calculations cannot be replicated in full. However, the results for Scotland, as reflected in Lord Ross' report, were as shown in Table 3.13 below.

<sup>179</sup> ie approximately 10,000 during the 1970s and approximately 13,500 between 1 January 1980 and 1 September 1991.

<sup>180</sup> The Expert Group was set up by the Scottish Executive to consider the financial and other support offered to patients who were infected with Hepatitis C as a result of a blood transfusion or treatment with blood products. It published a preliminary report in November 2002 and a final report in March 2003. Paragraph 4.8 of the Expert Group's final report sets out the figures provided by Dr Soldan. Final Report at <http://www.scotland.gov.uk/Publications/2003/03/16844/20519>

<sup>181</sup> Letter dated 24 July 2002 by Dr Brian McClelland to Mr Bob Stock, Special Adviser [SGH.005.7201], enclosing a copy of Dr Soldan's *Estimated Number of Individuals Infected by Blood Transfusion in Scotland* [SGH.005.7203]

<sup>182</sup> Dr Soldan, *Estimated Number of Individuals Infected by Blood Transfusion in Scotland* [SGH.005.7203]

<sup>183</sup> The exercise had not been completed in 2002 and Dr Soldan can have had only preliminary or estimated data available.

**Table 3.13: Dr Soldan's Scottish estimates**

Number of individuals probably infected with HCV by blood transfusion 1980 to 1991			
	Total	Not known to be dead by 1995	Known/expected to be dead
Identified by HCV look-back programme in Scotland	106	106	0
Received components that entered look-back but did not receive testing in that programme	1243	628	615
Received components issued between 1 January 1980 and 31 August 1991 that did not enter the look-back programme in Scotland	2149	878	1271
Total	3498	1612	1886

**3.175** As noted above, the number identified and tested positive through the national look-back became 133 (Table 3.8), and an adjustment would be required for that change if for no other.<sup>184</sup> Dr Soldan's other data cannot be reconciled with the results of the look-back study. In this exercise the known infections accounted for a mere 3% of the total projected. Dr Soldan commented that many assumptions were used to generate her estimates, some of uncertain validity, and she had serious reservations about the application of her findings to individual cases.

#### *Health Protection Scotland*

**3.176** To assist the Inquiry, Professor David Goldberg and his colleague at Health Protection Scotland (HPS), Dr Christian Schnier, undertook a separate modelling exercise, in collaboration with the SNBTS, to estimate the number of people infected with Hepatitis C as a consequence of blood transfusion in Scotland during the period 1970–91 and the number who were alive as at June 2011.<sup>185</sup> Professor Goldberg explained the differences between his model and Dr Soldan's model as follows:

It should be understood that the model used by Schnier and Goldberg in 2011 for the Penrose inquiry was very different to that used by [Dr Soldan] ... in 2002. Further, the [Goldberg/Schnier] model was built following considerable consultation with Dr McClelland and Dr Gillon of SNBTS. The principal differences between the models is that the Soldan one used "lookback data" to inform its estimates and did not factor in any variation in HCV antibody prevalence among blood donors during 1980–31 August 1991. The Schnier and Goldberg model did not use lookback data to inform its estimates but did use estimates of HCV antibody prevalence among blood donors for each year during 1970–1991 ...

Schnier and Goldberg, in consultation with McClelland and Gillon, made the assumption that the size of the HCV infected IDU [injecting drug users] population in Scotland was directly proportional to the HCV infected donor population.

<sup>184</sup> Letter from National Medical & Scientific Director, SNBTS, to Dr Aileen Keel, Scottish Office, dated 28 April 1998 [SGF.001.2174] and Scottish Hepatitis C Lookback Results – 9 April 1998 [SGH.002.8669]

<sup>185</sup> *Estimation of the Number of Individuals Infected as a Consequence of Blood Transfusion in Scotland 1970–1991* – Goldberg and Schnier [PEN.018.1561]

In addition ... Schnier and Goldberg used a factor to account for the introduction of blood donor deferral in 1984 – a factor not used by Soldan et al.

Two other factors used by Soldan were modified for Scottish purposes; instead of the number of units generated from one blood donation being 1.6 (Soldan), the Scottish estimate, based on local data and expert opinion, was deemed to be 1.25; the proportion of units transfused was estimated to be 56% and not 66% (Soldan).<sup>186</sup>

**3.177** Using their statistical model, Professor Goldberg and Dr Schnier provided an initial estimate of the number of individuals in Scotland infected with Hepatitis C as a result of transfusion between 1970 and 1991.<sup>187</sup> That was followed up by a fuller document in the form of an academic paper.<sup>188</sup> In their paper they set out the various assumptions upon which their model was based.<sup>189</sup> The probability of a transfused blood component being infected with HCV was influenced by factors such as the size of Scotland's Hepatitis C infected population in any particular year and the effectiveness of the SNBTS' deferral policy during the period 1984–91. Direct evidence of the size of the HCV-infected population was not available, either in the Scottish population as a whole or in the population of Scottish blood donor.

**3.178** The available observed data comprised:

- The numbers of blood donations made during the period 1975–91.
- The prevalence of HCV antibody among individuals donating blood during September 1991 – February 1992.

**3.179** Assumptions were required for:

- The number of blood donations made by blood donors during 1970–74.
- The average number of blood components generated by a blood donation.
- The probability of a blood component being transfused.
- The probability of a transfused blood component being infected with HCV.

**3.180** The acceptability of the assumptions is fundamental to the exercise. The World Health Organization's Global Burden of Hepatitis C Working Group in 2004 (referred to in the Goldberg/Schnier paper) emphasised that precise estimation of the incidence of HCV infection was not possible, given available data. Professor Goldberg noted that it was possible only to estimate the numbers of individuals who had acquired infection through blood transfusion (or any other route). A combination of observed data and assumptions based on observation and expert opinion was employed to develop estimates.

**3.181** As in England, the first firm information on the prevalence of HCV antibody in blood donors in Scotland came with the collection of data on anti-HCV among blood donors during the initial months of HCV screening. Prevalence in Scotland over a period

<sup>186</sup> Letter dated 28 February 2012 from Professor Goldberg to Tracey Turnbull, [PEN.019.0896] at 0897, response to question 4

<sup>187</sup> *Estimation of the number of individuals infected as a consequence of blood transfusion in Scotland 1970–1991*, dated 3 and 5 October 2011 [PEN.018.1561]

<sup>188</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012 [PEN.019.0899]

<sup>189</sup> *Ibid* [PEN.019.0899] at 0900 and 0901

of six months was found to be 0.088%. For present purposes, an important parameter was the proportion of antibody-positive persons who were RNA virus-positive; that is infectious. The first material assumption made by Professor Goldberg and his colleague was that the appropriate proportion was 75% (assumption ii in the report). The other 25% of HCV antibody positive donors would have cleared the infection and would have been HCV RNA-negative, with the result that the prevalence of HCV-positive infectious donors in the donor population in Scotland in 1991 was estimated to be 0.066% (0.088, less 25%).<sup>190</sup> As with other parameters, uncertainty was reflected in their statistical model, which assumed values ranging from 50% to 85%.

**3.182** The basis for Professor Goldberg's assumption was the WHO advice provided by the Global Burden of Hepatitis C Working Group. It had among its key areas of study the natural history of HCV infection, including 'healthy individuals', morbidity and mortality. Other estimates have been made, and a clearance rate of 20% has been referred to.<sup>191</sup> There cannot be a single 'correct' value. Professor Goldberg's adoption of the WHO rate was justifiable in the absence of hard data suggesting a need for variation to account for local factors. It was within, though at the lower end of, the most up-to-date estimates reported by Dr Hay in the UKHCDO updated report of April 2012.<sup>192</sup>

**3.183** From the prevalence of 0.066% estimated for 1991, the next necessary step was to estimate the prevalence of infection in the donor population over the study period, beginning in 1970. There were no relevant observed data for that population. Prior to anti-HCV testing there were no available means of measurement. In developing their estimate of the number of people who acquired HCV infection as a consequence of blood transfusion in Scotland during the period 1970 to 1991, Professor Goldberg and Dr Schnier adopted the results of a study by Hutchinson, Bird and Goldberg, carried out by statistical modelling, which estimated HCV prevalence in injecting drug users (IDUs) between 1970 and 1991, and applied the trend brought out to work back from 0.066% to values for each year (assumption iv).<sup>193</sup>

**3.184** The Hutchinson study was based on local data from Glasgow for the prevalent number of IDUs per calendar year from 1960 to 2000. The data were adjusted for assumptions about age-related use, mortality from non-HCV causes and other factors, to bring out a pattern of the prevalence of HCV infection among current IDUs. The model was then adapted to the whole of Scotland based on available epidemiological data by adjusting for a number of key parameters. The paper was aimed at providing quantitative estimates of the current and future burden of HCV disease in the IDU population in planning a public health response to treatment needs and preventive measures. The characteristics of IDUs affecting HCV disease progression were discussed, and are reflected in the paper.

**3.185** Goldberg and Schnier assumed that the change in HCV prevalence among the blood donor population was proportional to the change in the estimated number of

<sup>190</sup> Ibid [PEN.019.0899] at 0901 and 0902. Note that the derivation of this value of 0.066% is different from Dr Soldan's derivation and use of the same numerical value in her calculations.

<sup>191</sup> See paragraph 3.122. Khan et al found a natural clearance rate of 17.4% among patients with congenital bleeding disorders studies in Scotland: 'Outcomes of hepatitis C infection in a large haemophilia population' [PEN.013.0008] as revised for publication February 2013. They noted that the natural clearance rate (and other factors), closely mirrored the non-haemophilic population. See also Dr Hay – Day 8 pages 41–43 for evidence of his clinical experience of higher rates of clearance.

<sup>192</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry, 2012* [PEN.019.0927] at 0983

<sup>193</sup> Hutchinson et al, 'Modelling the current and future disease burden of hepatitis C among injection drug users in Scotland', *Hepatology*, 2005; 42:711 [LIT.001.4373]

HCV-infected IDUs.<sup>194</sup> This was an important assumption. Injecting drug use continues to be both directly and indirectly the principal driver of Scotland's HCV epidemic. There is a direct impact from a donation by an infected injecting, or former injecting, drug user. An indirect impact resulted from a donor who had never used intravenous drugs but acquired HCV infection from an injecting drug user, sexually or through contact with needles or instruments in a healthcare/tattoo/barbershop setting. The Goldberg/Schnier assumption of proportionality reflected the view that approximately 90% of all individuals diagnosed with HCV in Scotland, for whom risk factor information was available, had injected drugs, and that 'an appreciable proportion' of the remainder acquired infection indirectly, by contact with an infected IDU.<sup>195</sup>

**3.186** In addition, the authors noted that in 1984 the SNBTS introduced a deferral policy aimed at reducing the number of donors who were at higher risk of transmitting blood-borne virus infection (ie the leaflets and questionnaires introduced from 1984 to try to exclude donors at a higher risk of transmitting HIV), and they assumed that the deferral policy reduced HCV prevalence in the blood donor population by a constant factor of 66% from 1984 onwards.<sup>196</sup>

**3.187** The progressive development from the 1970s and early 1980s of methods of identifying and deterring high risk donors from giving blood are discussed elsewhere in this Report at Chapter 26, *Donor Selection – Higher Risk Donors*, and Chapter 28, *Donor Selection – AIDS*. At this stage it is appropriate to note only that these steps were taken, and are likely to have reduced the incidence of infection in donations. There is a question related to the quantification of the immediate impact of the policy, and its sustained effect over the period to 1991, to which it will be necessary to return. However, some estimate of the impact of the deferral policy was necessary.

**3.188** Professor Goldberg and his colleagues set out in table 1 of their report<sup>197</sup> an estimate of the prevalence of HCV-positive infectious donors in Scotland as a whole before and after the introduction of donor deferral: that is from 1970 to 1983 and from 1984 to 1991 respectively. The table reflected in the first place the Hutchinson data and the assumption that the change in prevalence among donors was proportional to the estimated change in prevalence among IDUs (paragraph 3.183) and in the second place the assumption that the deferral policy reduced prevalence in the donor population by 66% from 1984. The prevalence in the donor population for each year between 1970 and 1991 which these assumptions generate has been plotted in Figure 3.5.

<sup>194</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012 [PEN.019.0899] at 0902. The estimated number of HCV-infected IDUs in Scotland is shown in appendix 8 of the Goldberg/Schnier paper, [PEN.019.0899] at 0911. The estimated number of IDUs rises from 575 in 1970 to 996 in 1975, 2857 in 1980, 10,689 in 1985 and 18,244 in 1990. These estimates are, in turn, based on the paper by Hutchinson *et al*, 'Modelling the current and future disease burden of hepatitis C among injection drug users in Scotland', *Hepatology*, 2005; 42:711 [LIT.001.4373]

<sup>195</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012, Assumption iv [PEN.019.0899] at 0900

<sup>196</sup> *Ibid* [PEN.019.0899] at 0902

<sup>197</sup> *Ibid* [PEN.019.0899] at 0902

**Figure 3.5: Effect of Goldberg/Schnier assumptions relating to HCV Prevalence in blood donor population in Scotland**

**3.189** The rapid build-up of prevalence to 0.067% in 1983, reflects directly the assumed correlation of the growth in the number of IDUs and in HCV prevalence in the donor population. From 1984 to 1991, the assumption was that the donor deferral policy consistently reduced the number of infected donations. Professor Goldberg was asked whether a degree of gradation should have been assumed, to allow time for the policy to take effect. He explained that alternatives had been tested, and that it had been concluded that, although the rate selected was intuitive, it was thought optimal.

**3.190** Professor Goldberg's first and seventh assumptions (as listed in the report) were the same as Dr Soldan's: that every recipient of a contaminated unit subsequently developed HCV infection, subject to 'discount' for those who cleared the virus or were never to progress to chronic liver disease, and that the risk of an individual receiving two or more infected units was negligible. In the stochastic model some of the assumptions were modified to express uncertainty.

**3.191** In their stochastic exercise, Professor Goldberg and Dr Schnier estimated that between 1970 and August 1991, a median number of 1533 individuals were infected with Hepatitis C as a result of blood transfusion (the median estimate of 1533 was derived from a lower estimate of 1198 and an upper estimate of 1963).<sup>198</sup> An estimated breakdown per year is provided in table 3 of the paper, which indicates that an estimated median number of 232 individuals were infected with Hepatitis C between 1970 and 1979 and 1026 individuals were infected between 1980 and 1989.<sup>199</sup> In the year prior to HCV screening of donors being introduced (ie 1990), it was estimated that 155 individuals were infected with HCV as a result of transfusion.<sup>200</sup>

<sup>198</sup> Ibid [PEN.019.0899] at 0904

<sup>199</sup> Ibid [PEN.019.0899] at 0904. A footnote to Table 4 states, 'Total statistics are results from simulation and do not equate to the sum of the simulation results by year between 1970 and 1991'.

<sup>200</sup> Ibid [PEN.019.0899] at 0904

**3.192** Based on the assumptions set out in their paper, the authors also estimated that a median number of 296 individuals who were infected with Hepatitis C as a result of transfusion were alive in 2011, of whom 222 were RNA positive (on the assumption that 25% of the 296 cleared the virus and were no longer RNA positive).<sup>201</sup>

**3.193** At least some of the assumptions made by Professor Goldberg and Dr Schnier cannot be verified, and the validity of the figures produced by their statistical model, like the figures produced by other statistical models, is necessarily qualified. If different assumptions and input data are used, different figures are generated.

### *Evidence relating to the statistical models*

**3.194** In discussing Dr Soldan's exercise, Professor Goldberg said that there was a potential bias in the exercise, in particular in applying the same factors to deceased recipients and living recipients who had not been tested, as applied to those who followed the observed path to the end.<sup>202</sup> The difficulty is clearer in the case of the deceased recipients. They were not available for testing. The assumption that the proportion of positive tests derived from testing the living could be applied directly to those who had died is obviously not valid, especially where, as here, the proportion of individuals known or assumed to have died is so high. As Professor Goldberg observed, there must have been reasons why 38% of those assumed to have been alive were not tested.<sup>203</sup>

**3.195** Professor Goldberg said:

But the thing is that the extrapolations appear to be based on the [observed path] and the question is: can you extrapolate? Because there may well be biases in the system which mean that the numbers infected, or the expected numbers infected, may be an underestimate or an overestimate.<sup>204</sup>

**3.196** Commenting principally on Dr Soldan's material, Professor Goldberg said:

I'm not convinced this is the only way to estimate the size of the infected population. I think there are other ways of doing it ... if you use a combination of approaches, then you do reduce uncertainty. But that all takes time and much, of course, is dependent on the information that's available to you. So for Scotland we have information generated through the look-back, but we also have other information about the size of the infected population, ie Scottish population, during the 1980s but also during the 1970s as well. So I would expect to use these data.<sup>205</sup>

And:

[I]f you just use one method, you are opening yourself up a little. I mean, you know, this is actually a very good piece of work undertaken by Kate, who probably knows more about this field than anybody else in the UK. But it does have its limitations and I think we just have to acknowledge these limitations  
....

By and large, when you are doing this sort of work, if you use maybe two or three methods – but much depends of course on the information you have

<sup>201</sup> Ibid [PEN.019.0899] at 0905 to 0909

<sup>202</sup> Professor Goldberg – Day 6, pages 129–130

<sup>203</sup> Ibid, page 130

<sup>204</sup> Ibid, pages 130–131

<sup>205</sup> Ibid, pages 127–128

available to you – I think your confidence in your final outcome is very much greater because if you have considerable differences in your results, you can get an average or you can take what's regarded as the best or whatever.<sup>206</sup>

**3.197** These observations appear to be as relevant to the Goldberg/Schnier model as to Dr Soldan's exercise. Professor Goldberg and Dr Schnier were asked by the Inquiry to re-run their model, omitting the assumption that the donor deferral policy introduced in 1984 reduced the HCV prevalence in the blood donor population constantly by 66%. In response to that request Professor Goldberg advised:

We repeated this modelling exercise to ascertain the impact of (i) a deferral policy with no effect and (ii) a deferral policy, the effect of which increased incrementally between 1983 and 1991. For (i) the number infected until 1991 was estimated to be 1110 (90% credibility interval: 876 to 1413), the number alive as at 2011 was 230 (178 to 294) and the number alive as at 2011 and chronically infected was 173 (128 to 225). For (ii) the estimated number of those infected was 2212 (1657 to 2853), the number alive as at 2011 was 438 (325 to 566) and the number alive and chronically infected as at 2011 was 326 (241 to 435).<sup>207</sup>

**3.198** Professor Goldberg and Dr Schnier were also asked to re-run their model, this time omitting the assumption that the HCV prevalence in the donor population between 1970 and 1990 was directly proportional to the estimated prevalence of HCV in the injecting drug use population. They did so by adopting an approach similar to that of Dr Soldan, and assumed a flat rate based on 1991 data. Professor Goldberg replied:

We modified the model, as requested, using a constant HCV prevalence (0.09% antibody positivity); this generated an estimated infected number of 6784 (5027 to 8776), with the number having survived until 2011 being 1050 (789 to 1364) and the number having survived as at 2011 and being chronically infected, 788 (569 to 1044).<sup>208</sup>

At this stage it is sufficient to note that the changes in assumptions reflected in this paragraph and in paragraph 3.205 below generate very large variations in outcome.

### *HCV infections as a result of blood transfusion between 1970 and 1991: discussion and conclusions on statistical models*

**3.199** As Professor Goldberg accepted, neither of the statistical analyses carried out provided a single, wholly acceptable source of evidence. A sensitivity analysis was not carried out to test the assumptions made in varying conditions.<sup>209</sup> It will be necessary to look at the evidence in the round to determine whether one can make an estimate of the incidence of infection in NHS patients using recorded data and acceptable assumptions.

**3.200** There is one point common to the exercises: the use of relatively low levels of known and objective data of HCV transmission. In Dr Soldan's English paper the known data (derived from the HCV look-back programme in England) accounted for 5% only (677/13,505) of the

<sup>206</sup> Ibid, pages 132–133

<sup>207</sup> Letter from Professor Goldberg in response to further queries on statistics from Professor Oliver James [PEN.019.0922] at 0923, assumption 3

<sup>208</sup> Ibid [PEN.019.0922] at 0924, assumption 4. For completeness, it should be noted that Professor Goldberg added, 'It is my view that the approach used, ie that using the HCV infection IDU estimates, is a novel and scientifically valid one.'

<sup>209</sup> Professor Goldberg – Day 6, pages 134–135

total infections estimated to have been transmitted by transfusion between 1 January 1980 and 1 September 1991. That is a low proportion of known instances of transmission relative to the estimated total. The percentage was higher in the case of patients who survived to 1995, at 13%. The median age of these patients in 1995 was 55 years, significantly lower than the median age of the identified recipients in the group of 3373 added by extrapolation.<sup>210</sup> On any approach, the projections were very heavily dependent on the validity and accuracy of the assumptions made, and that affects the level of confidence in the result. Dr Soldan's paper recognised that.<sup>211</sup> In her Scottish exercise, the known data accounted for 3% of the total infections estimated, which was an even lower proportion.

**3.201** Dr Soldan's application of a constant infectivity rate, derived from the first four months after testing began on 1 September 1991 in England and the initial six months of testing in Scotland, to all donations for the period 1 January 1980 to 1 September 1991, appears to raise a problematic issue.<sup>212</sup> It was one of the features considered by Professor Goldberg to be significant in comparison with his own approach. It assumed that this component of the risk of transmission of infection remained the same throughout the 12 years of the period of study. That is not consistent with a picture in which HCV infection rates were increasing as a result of the practices of intravenous drug users, for example, or, more generally, with the impression that HCV infection in the general population appears to have grown significantly over the 1970s and 1980s.

**3.202** The increase in HCV prevalence in the general population was one of two relevant countervailing trends over that period. The other was the increasing proportion of potential new and returning blood donors, who were dissuaded from donating blood from the commencement of self-deferral policies onwards, by increasing efforts to discourage 'high risk' individuals from presenting at donor sessions to give blood. The deferral of potential blood donors who were at higher risk of blood-borne virus infection, implemented generally in 1984 in the AIDS period, is likely to have had some incidental impact on the risk of transmission of HCV. For that reason alone, the HCV infectivity rate prior to 1984 might have been higher than in the period from 1984 onwards.

**3.203** Another element in the exercise that may have been important was the yield of components per donation assumed in the calculation. The yield in England, based on measurement there, was 1.6 components per donation. In the later Goldberg/Schnier exercise the Scottish yield applied was 1.25 components per donation. There were two possible reasons that may have contributed to the difference. Blood collection in Scotland was plasma-driven in the 1980s and an excess of red cells was inevitable. Dr Gillon speculated that there would have been a higher rate of discard in Scotland, reducing the number of components transfused.<sup>213</sup> That is a reasonable speculation. In addition, excess Scottish red cell production was 'exported' to England, reducing the proportion of components produced that were actually used in Scotland.

**3.204** Dr Soldan did not deal with these issues. It cannot be over-emphasised that it is accepted that Dr Soldan's work was a ground-breaking attempt to provide an estimate of the extent of the problem of post-transfusion HCV infection. The issues that may arise

<sup>210</sup> Soldan *et al*, 'The contribution of transfusion to HCV infection in England', *Epidemiology and Infection*, 2002; 129:587–591 [PEN.013.1580] at 1581–2 and 1583.

<sup>211</sup> *Ibid* [PEN.013.1580] at 1583

<sup>212</sup> It should be noted that although Dr Soldan and Professor Goldberg used an infectivity ratio of 0.066% they were derived quite differently. Professor Goldberg's value was the observed Scottish rate of 0.088% discounted by 25% for the proportion assumed to be non-infective.

<sup>213</sup> Dr Gillon's response to further questions on statistics [PEN.019.1311] at 1312

from her original work do not have to be resolved so far as they relate solely to England. That is not within the scope of the terms of reference of the Inquiry. Some, however, have an indirect bearing on the figures brought out for Scotland.

**3.205** Statistical modelling is a complex exercise and may be influenced by the interaction of other values. It has to be emphasised that while it is relatively easy to draw negative conclusions on the assumptions made, that does not assist in providing a reliable estimate. Simple arithmetical adjustment for a single altered factor in a statistical analysis would be unsatisfactory. One cannot substitute one value for any given factor for another and express a different conclusion arithmetically. For example, if Dr Soldan did use the component yield observed in England (1.6 units per donation) in her Scottish exercise, that would have been one-third higher than the Goldberg/Schnier figure. The effect is likely to have been large. Without knowing the sensitivity of the model to a variation of that kind, the consequence in terms of the final number could not be estimated broadly.

**3.206** Professor Goldberg considered that the extrapolation of the data from the observed path to the other components was a reasonable approach, though not the only approach. As already commented (paragraph 3.164), Dr Soldan's approach was not seriously disputed in the evidence before the Inquiry, and it is appropriate to take the results of her calculations into account.

#### The Department of Health estimate and Dr Soldan's estimate for Scotland

**3.207** While the methodology for the DoH estimate of the total number of TT HCV infections in the United Kingdom between 1970 and 1991 is not clearly expressed, it seems likely that it is an extrapolation of Dr Soldan's figure for England, to take account of the whole UK population. On that basis, as noted above at paragraph 3.170, it is possible to back-calculate the DoH estimate and to suggest that the estimate for Scotland would be about 9% of 28,043, ie 2524.

**3.208** This figure for Scotland is significantly different from the figure brought out in Dr Soldan's original Scottish exercise. Her value of 3498 related to components issued from 1 January 1980 to 31 August 1991; it was already higher than the number deduced from the UK values for a much longer period. In relation to England, the assumption of 10,000 additional infections for the previous decade amounted to 74% of the estimate for the later period. Since that involved application of the same general assumptions for both periods, one might expect an equivalent approach to estimating figures for Scotland to have produced an additional number of about 2600, making the Scottish number about 6100 for the whole period 1970–1991. Adopting a flat HCV donor prevalence rate of 0.09%, and applying his model, Professor Goldberg later calculated a median value of 6784 for this period. The difference between 6100 and 6784 is not material given the margins of error implicit in the exercise. On either approach, the total for England and Scotland would already exceed the DoH total for the United Kingdom, and leave no room for numbers of infections in Wales and Northern Ireland.

**3.209** It is not possible in the circumstances to accept Dr Soldan's estimate for Scotland as a sufficient and acceptable basis for discussing the numbers put at risk in Scotland. Dr Soldan was not available to assist the Inquiry by reassessing the position.<sup>214</sup> Her estimate remains one result of statistical modelling. Without detailed examination, it cannot be

<sup>214</sup> Letter from Health Protection Agency dated 25 June 2010 [MIS.001.0299]

dismissed. On the other hand, the DoH figure of about 2500 for Scotland, while not supported by detailed description of methodology, has the benefit of proportionality, and has at least superficial support from that fact.

### The Goldberg/Schnier model

**3.210** As already indicated, there were two critical assumptions in the Goldberg/Schnier model that required particular examination: the adoption of the rate of growth of HCV infection in injecting drug users as the rate of change of HCV prevalence both in the population as a whole and in the donor population, and the impact of the SNBTS blood donor exclusion policy in and after 1984.

**3.211** The sensitivity of the Goldberg/Schnier model to variations in the prevalence of HCV infection in the donor population was demonstrated by the re-run of the model excluding the assumption that HCV prevalence in the donor population was directly proportional to the estimated prevalence in the IDU population. Irrespective of the numbers brought out, the assumption was significant.

**3.212** It appears to the Inquiry that proportionality implied both that:

- There was a direct relationship between the pattern of HCV prevalence in the general population of Scotland and the growth in the numbers of injecting drug users.
- There was a direct relationship between the pattern of HCV prevalence in the general population and in the blood donor population over the relevant period.

**3.213** Overall, the evidence before the Inquiry showed that the growth in numbers of HCV-positive IDUs came to be the major factor to influence the prevalence of HCV infection in the Scottish population as a whole. The issue for the Inquiry was whether the data supported the assumption of direct proportionality of relationship between the IDU population and the general population of Scotland between 1970 and 1990 (assumption iv). That was explained:

The rationale of assuming proportionality is that it is estimated that 90% of HCV infected individuals in Scotland acquired Infection directly through injecting drug use and that an appreciable proportion of the remainder will have acquired infection indirectly as a consequence of injecting drug use (eg being born to an infected IDU or having unprotected sex with an infected IDU) (Hutchinson et al., 2006)<sup>215</sup>

**3.214** The paper by Hutchinson and others published in 2006<sup>216</sup> analysed information on diagnosed HCV infection at December 2004, (18,571 individuals less 11% who had died, 16,500 net), and estimated the likely pattern of infection in 33,500 antibody positive individuals who had not been diagnosed. Allowance was made for 25% natural clearance. In each case 88% of chronic HCV-infected people were estimated to be IDUs and 12% were non-IDU's; 26.6% of whom were blood/blood factor recipients.

<sup>215</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012 [PEN.019.0899] at 0900

<sup>216</sup> Hutchinson et al, 'Hepatitis C Virus Infection in Scotland: Epidemiological Review and Public Health Challenges', *Scottish Medical Journal*, 51; 8:15: [LIT.001.3943]

**3.215** The 2006 paper carried forward by a year a 2005 study by Hutchinson, Roy and others<sup>217</sup> of information to December 2003 which had, in turn, drawn on material from a 2004 paper by Professor Goldberg's group at the Scottish Centre for Infection and Environmental Health (SCIEH).<sup>218</sup> The 2004 paper noted that at 31 December 2003 a total of 18,109 individuals were known to be HCV antibody positive. 61% of those were known to have injected drugs at some time. Those individuals represented 90.5% of the total for whom risk information was available (67% of the total of 18,109).

**3.216** The SCIEH paper contained a detailed analysis of data for each NHS Board, and for Scotland as a whole, aggregating data to 1995 and thereafter presenting data annually. For the period to 1995 'blood factor'<sup>219</sup> accounted for 269 reported cases of HCV antibody-positive individuals, and IDUs accounted for 1029, a ratio of just under 1:4. For 1995 the ratio was 29:648: 1:22. Over the remainder of the period reported the ratio of 'blood factor' antibody positive recipients to IDUs continued to fall.

**3.217** It would have been inappropriate to subject these papers to further, more detailed critical analysis. It did not appear that the additional time and expense involved in instructing further expert opinion was justified, since it was clear that a further or different set of assumptions would be unlikely to result in a definitive conclusion. It is not inappropriate to note that the data underpinning the opinions expressed have at no time been comprehensive. Perhaps more significantly in terms of long term trends, inferences have been drawn from reference periods including the highest growth in HCV positive IDUs when, by sheer force of numbers, they were clearly the dominant factor affecting HCV prevalence in the general population. As the SCIEH report notes, for blood factor concentrate recipients there were no new infections after the introduction of effective heat treatment of factor concentrates in the mid-1980s.<sup>220</sup> From 1991 screening for antibodies to HCV prevented new infections from transfusion generally. Mortality among transfusion recipients was at all times skewed by the significant proportion of NHS patients who died within a short time of the procedure that had required transfusion.

**3.218** The Inquiry cannot exclude the direct linear numerical relationship between the increase in HCV among IDUs and the increase in the donor population over the period 1970 to 1991. It seemed appropriate, however, to seek further explanation of its basis. In relation to the principal issue raised with him, Professor Goldberg explained:

You contest that the change in HCV prevalence among blood donors over the two decades in question would not have mirrored the change in the estimated number of prevalent infections among injecting drug users over this period. While we cannot prove this was indeed the case, our view is that injecting drug use has been the principal driver of HCV infection in Scotland, even going back to the 1960s. As we pointed out, it was not just the direct effect but

<sup>217</sup> Hutchinson *et al*, 'Modelling the current and future disease burden of hepatitis C among injection drug users in Scotland', *Hepatology*, 2005; 42:711 [LIT.001.4373]

<sup>218</sup> Codere *et al*, 'Surveillance of known hepatitis C antibody positive cases in Scotland: Results to 31 December 2003', *SCIEH Weekly Report* [LIT.001.4176] at 4177

<sup>219</sup> In these data 'blood factor' numbers appear to refer exclusively to those who acquired HCV infection through coagulation products: footnote at page 4177. Transfusion recipients were included in the 'other' or 'not known' categories. This classification continues in the HPS Weekly Report for 23 October 2013; Volume 47 No. 2013/43; ISSN 1753-4224 (Online): <http://www.documents.hps.scot.nhs.uk/ewr/pdf2013/1343.pdf>. Table 2. The 'Other' category includes needlestick, bite, blood spillage, and blood transfusion, among other means of transmission. By comparison, the data in the Hutchinson paper of 2006 encompasses all transfusion-transmitted infections.

<sup>220</sup> Codere *et al*, 'Surveillance of known hepatitis C antibody positive cases in Scotland: Results to 31 December 2003', *SCIEH Weekly Report* [LIT.001.4176] at 4177

also the indirect one. What we mean by this is that people who did not inject drugs but acquired their infection through, for example, tattooing, are likely to have become infected with a virus which was originally circulating among individuals who injected drugs ...<sup>221</sup>

It seems appropriate to be cautious about accepting total equivalence, as is implicit in the exercise.

**3.219** The next step seems superficially difficult, involving the assimilation of the prevalence of infection in the general population and in the blood donor population. It appears generally to have been accepted that there were always significant differences between the prevalence of HCV infection in the blood donor and general populations, and that these had become more pronounced since the early 1980s. The donor population has always been selected by age and general health factors and, at least in parts of Scotland, by questioning about injecting drug use and observation of signs of injecting. In Professor Goldberg's view, the prevalence of HCV in the general population may have influenced the prevalence in the donor population to a greater extent in the past than in more recent times.<sup>222</sup> In general, however, a policy of deferral on the basis of intravenous drug use, despite the limitations inherent in the practices of the SNBTS donor teams, must have had some impact on the risk of IDUs both being accepted as donors, and giving blood that entered the pool of blood available for clinical use.

**3.220** There were, and are, demographic distinctions between the general population and the blood donor population. It is not at all clear that the cohort of HCV antibody-positive individuals coming to the notice of doctors as being IDUs was ever a major component of the blood donor population (and it is to be borne in mind that between 80 and 90% of that population are return donors). Some return donors at 1991 will have begun donating decades earlier, in some cases before injecting became a major issue.

**3.221** Assumption (iii) in the Goldberg/Schnier model was:

Deferral policy, introduced by SNBTS in 1984, was assumed to have reduced the HCV prevalence in the donor population constantly by 66%. This assumption was based on limited local data and expert opinion.<sup>223</sup>

**3.222** The 'local data and expert opinion' referred to information and advice provided by Dr Gillon and Dr McClelland. The paper explained:

In 1984, SNBTS introduced a deferral policy to reduce the number of donors with a higher risk of having blood born (sic) virus infections; therefore the prevalence of HCV-positive donors in the donor population during 1984 to 1991 was lower than it would have been, if the deferral policy had not been in operation. It was assumed that the deferral policy reduced HCV-prevalence in the donor population by 66%.<sup>224</sup>

**3.223** The need for an adjustment to reflect the general point made is clear and is accepted: the deferral policy must have had some impact, whenever it was implemented.

<sup>221</sup> Letter from Professor Goldberg in response to further queries on statistics from Professor Oliver James [PEN.019.0922] at 0923

<sup>222</sup> Professor Goldberg – Day 6, pages 96–97

<sup>223</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012 [PEN.019.0899] at 0900

<sup>224</sup> Ibid [PEN.019.0899] at 0902

The year 1984 was perhaps too early in the evolution of SNBTS management systems to find that there was a 'policy' introduced by SNBTS: the era of regional autonomy had not yet passed, and there were variations in the dates when practice changed across Scotland. Further, as already noted, the policy of Edinburgh and south east Scotland, which became the basis of the general model, still reflected an erroneous view of the duration of risk presented by a carrier of HCV RNA. The question was whether 66% was an acceptable estimate for the impact of the policy change from 1984 to 1991.

**3.224** The Goldberg/Schnier number of 6784 recipients of HCV-contaminated units, was based on a flat rate prevalence of 0.09%. Even at that level, the contaminated units remain a tiny percentage of the total number of units transfused, at 0.16%. The Goldberg/Schnier data showed that 4,344,795 units were transfused over the period 1970 to 1991. In terms of the numbers of donors presenting, the percentage is even lower. Over the beginning of the period when voluntary deferral was in practice, SNBTS data on donors and deferrals indicate the difficulty in drawing inferences. The pattern was as shown in Table 3.14.<sup>225</sup>

**Table 3.14: Donors and donors deferred 1981–82 to 1987–88**

**SNBTS**

	Total attendances		New donor attendances	
	Attended	% deferred	Attended	% deferred
1981–82	322,304	9.30	51,729	16.5
1982–83	328,086	9.10	50,241	14.5
1983–84	336,802	8.10	54,046	12.5
1984–85	338,278	9.00	50,004	9.5
1985–86	341,307	8.59	48,858	15.8
1986–87	340,890	8.78	48,350	13.5
1987–88	323,837	9.10	39,580	13.6

**3.225** In relation to total attendances, the fall in the number of donors influenced by a change in deferral policy is problematic. These were individuals whose blood had been accepted, perhaps often, in the past or who had been deferred temporarily and had returned. In 1984–85 approximately 30,500 return donors were deferred. These were, by definition, individuals who had not been deterred by the policy from attending to offer blood. None who attended and were deferred on grounds of evidence of intravenous drug use could be included with those persuaded by the leaflets and other material to self-defer. The number deterred by the policy and not attending at all must be speculative. There was a significant fall in new donors presenting at centres in 1985–86, and there was a relatively high incidence of deferrals in that cohort in that year alone compared to subsequent years. If it were possible to draw any inference from these data, it would be that the reducing numbers of new donors might have reflected the effectiveness of the policy more than would the numbers of return donors. The year on year cumulative

<sup>225</sup> The SNBTS data relate to years ended 31 March. However, applying the percentage deferral rates for total attendance, and averaging to accommodate the timing differences, the data reconcile reasonably closely with the Goldberg/Schnier data for observed donations.

reduction in new donors attending between 1983–84 and 1987–88 was 27%. The increase in deferrals in the new donor group after 1984–85 might suggest that other factors were affecting the situation.

**3.226** There is a danger in using the figures set out in Table 3.14 directly. The numbers of infected donors, returning and new, would be small relative to the totals in each group, and the relative percentage movements might have been affected by quite small changes in numbers. For the period September to December 1991, there were 33 infected donations from new donors. The number for 1992 was 55. They were, of necessity, included in the numbers who were not dissuaded from giving blood. One cannot tell what number would have attended to give blood but for the impact of the policy change, although it is not obvious that it would be large.

**3.227** Dr McClelland and Dr Gillon were asked to reconsider this area. From their responses, it appears that, with very limited relevant factual data, they attempted to make a conservative estimate.<sup>226</sup> Dr Gillon's explanation tends to underline the lack of numerical underpinning for the estimate:

We knew that the donor selection procedures introduced by November 1984, including as they did a signed declaration by each donor that he or she was not in the defined risk categories, led to the exclusion of a steady number of such donors throughout the period leading up to HCV screening in 1991. I received a written confidential report on every such donor, and therefore had first hand, if somewhat impressionistic knowledge of the apparent effectiveness of the procedures. In order to try to give this a numerical basis, we tried to extrapolate backwards as best we could from the reports on population prevalences published in the early 1990s and subsequently, in order to estimate what proportion of potentially infected donors we were managing to exclude ....

After commenting on HIV among intravenous drug users in Scotland, the discussion continued:

[W]e knew that the initial period of screening for HCV in 1991/2 produced a donor prevalence of 0.09%. Balogun et al (2002) estimated that the population prevalence in England and Wales peaked in 1986, at just over 1%. By 2005 the HPA (Hepatitis C in the UK. 2011 Report) estimated a prevalence in adults of 0.67%.

We interpreted these data as evidence that the entirety of donor selection policies and procedures, including publicity and donor education, reduced the risk of an infectious unit entering the blood supply by at least an order of magnitude ... We agreed in discussion that it would be appropriate to be very conservative in the final assumption, but we acknowledge that there are residual reservations about the assumptions on population prevalences. It was therefore correct to state that Assumption 3 derived in part from our expert professional opinions.

---

<sup>226</sup> Dr Gillon's response to further questions on statistics [PEN.019.1311] and Dr McClelland's response to further questions on statistics [PEN.019.1315]

**3.228** The Goldberg/Schnier report noted that 149 of 180,000 donors tested in the study period from September 1991 to February 1992 tested HCV antibody-positive. The adjusted value of 0.066% was the prevalence among those who presented at donor sessions, a cohort within the general population of potential donors but not co-extensive with that population. It was a difficult exercise to retrospectively apply that prevalence on the basis of limited data on the prevalence overall, whether in the IDU population or in the general population.

**3.229** Neither Dr Gillon nor Dr McClelland offered any computational support for the percentage applied in the Goldberg/Schnier exercise, nor any source data that were relevant to the estimate. It remains heavily dependent on limited data, their local knowledge and their professional judgement. Their local knowledge and their professional judgement are undoubtedly wide-ranging, and generally reliable, but cannot be assumed to be infallible.

**3.230** So far, this assumption has been discussed in terms of Scotland as a whole, as it was presented, and by reference to the time-frame selected. There are grounds for concern that detailed aspects of the assumption may not stand examination. The introduction of a deferral policy has to be set in context of other steps taken to reduce the risk of transmission of hepatitis, and the differing chronologies that emerged across Scotland. As discussed in Chapter 26, *Donor Selection – Higher Risk Donors*, collection of blood in penal institutions had been phased out by 1984. Edinburgh and South East Scotland BTS last collected blood from prisons in 1981; with the exception of Glasgow and south west Scotland, all other regions last collected in prisons in 1983; Glasgow and south west Scotland made their final (and much reduced) collection in 1984.<sup>227</sup> Though a small percentage of total collections while the practice of prison sessions continued, they carried a disproportionately high level of risk of transmission and, if the policy was valid, its implementation must have affected the prevalence of HCV infection in the donor population before the revised deferral policy came into effect.

**3.231** There were policy differences underlying the differing dates of phasing out of prison collections. There were similar policy differences relating to minimising the risk of transmission by donor selection and self-deferral. In Edinburgh and south east Scotland, Dr McClelland drafted a leaflet in 1983 promoting self-deferral.<sup>228</sup> It was tabled at a meeting of the SNBTS Coordinating Group on 24 May 1983.<sup>229</sup> At that meeting Dr Mitchell commented that he had introduced to the donor health questionnaire a question inviting those who were worried about AIDS to consult the doctor at the session. The Glasgow leaflet did not include a question on whether the donor had ever injected drugs, nor did a donor leaflet seemingly in use in England and Wales in 1983.<sup>230</sup> Dr Urbaniak, Director in the Aberdeen Centre, had decided after consideration not to do anything locally.<sup>231</sup> Dr McClelland's leaflet attracted adverse criticism from the Scottish Homosexual Rights Group.<sup>232</sup> Following constructive dialogue, a revised form of the leaflet was prepared. The

<sup>228</sup> Chapter 28, *Donor Selection – AIDS*, paragraph 28.8

<sup>229</sup> *Ibid* paragraph 28.11

<sup>230</sup> The leaflet is [SGF.001.0397] and was enclosed with a letter dated 12 September 1983 by Dr Entwistle, Chairman of the Working Group on the Selection and Care of Donors, to Dr Brookes, Director of the Dundee and East BTS, who was the Scottish representative on the working party [SGF.001.0375]. Professor Leikola was examined on how donor sessions were conducted in Finland and did not think that the donor questionnaire in use in Finland in the late 1970s/early 1980s included a question on whether the donor had ever injected or used drugs. That changed in 1983 with the arrival of AIDS: Day 13, pages 20 and 73.

<sup>231</sup> Minutes of SNBTS co-ordinating group meeting on 24 May 1983 [SNB.003.7116] at 7120

<sup>232</sup> Chapter 28, *Donor Selection – AIDS*, paragraph 28.15

revised form was distributed on 15 June 1983.<sup>233</sup> The position in other regions remained as before. There was now a second significant, though relatively short-lived, difference in policy between Edinburgh and south east Scotland and the rest of the country that had the potential to affect the prevalence of infection in the donor population.

**3.232** A leaflet for UK-wide distribution was ready for use by 1 September 1983.<sup>234</sup> It seems likely that it was available in Glasgow and the west of Scotland thereafter.<sup>235</sup> However, the means of distribution and the terms of the leaflet continued to attract debate. The tortuous process of revision of the text, and of the steps to be taken for distribution, saw major developments in February, June, August and November of 1984.<sup>236</sup>

**3.233** On 9 February 1984 at a meeting on the infectious hazards of blood products at the National Institute for Biological Standards and Control (NIBSC), attended by Drs Cash and McClelland, it was reported that:

The policies adopted in Scotland to minimise the risk of transmission of infection were explained. The three main strategies were 1) avoidance of high risk communities (such as prisons, known homosexual areas, etc); 2) detection of clinical abnormalities by examination and careful questioning; 3) exclusion of the high risk donor, or his blood ....<sup>237</sup>

**3.234** Against this background the selection of a date, or period, when deferral policy had a significant impact on the risk of transmission of NANB hepatitis in Scotland is problematic, as is the rigour with which deferral may initially have been carried out. There was no uniformity of policy or practice between the two major transfusion regions. The cessation of prison donation sessions had already altered the distribution of risk by excluding one potentially major contributor to the total pattern of risk, but so recently that its impact on total risk cannot have been known.

**3.235** Dr Hay emphasised that it was difficult to know the extent to which donor self-exclusion reduced the number of donors presenting a risk of transmission of infection, because HIV testing began shortly after the self-exclusion programme started. He proceeded on the basis that HIV testing and donor self-exclusion taken together reduced the number of high-risk donors giving blood.<sup>238</sup> He reported:

It is difficult to quantify the effect of donor self-exclusion and HIV testing on the risk of non-A, non-B hepatitis because there were no reliable diagnostic criteria for non-A, non-B hepatitis in the early 1980s. The prevalence of chronic non-A, non-B hepatitis also varied geographically. The condition appears to have been commoner in the USA than in Northern Europe. Contemporary studies suggest that the prevalence of non-A, non-B hepatitis in Northern European blood donors was approximately 0.4–1.0% in the early 1980s. In contrast, Contreras reported a much lower rate of infectivity of 0.085% per donor unit amongst 387 UK patients transfused an average of 3 units of blood each in 1987 and tested using an hepatitis C antibody ELISA. This suggests an approximately tenfold reduction in the risk of post-transfusion hepatitis C, in

<sup>238</sup> Dr Hay's report to the Inquiry on communication to patients about hepatitis 1974–1995 [PEN.018.1186] at 1191

the UK during the course of the 1980s, following the introduction of donor self-exclusion and HIV testing ...<sup>239</sup>

**3.236** He explained further in oral testimony. The risk groups for Hepatitis C and for HIV were similar and steps to exclude one virus would have an effect on attempts to exclude the other. While this would not make much difference to the risk from the concentrate derived from plasma in a large donor pool, the risk of transmission from single donor units such as cryoprecipitate or red cells was considerably reduced.<sup>240</sup>

**3.237** Other assumptions in the Goldberg/Schnier model included the yield of components per donation (1.25) which was a value provided by Dr Gillon and agreed by Dr McClelland.<sup>241</sup> The value was derived from data generated by the SNBTS look-back. SNBTS national statistics for the period 1981–82 to 1993–94 suggest that the yield of 1.25 was reasonably accurate. As calculated by the Inquiry, units placed at issue per donor,<sup>242</sup> including total cryoprecipitate, varied over the period but ranged between 1.18 and 1.31. The yield adopted was therefore an appropriate value for the purpose of estimating the number of recipients put at risk.

**3.238** Similarly, the assumption (number 6 in the Goldberg/Schnier list) that 56% of the donated blood was assumed to have been transfused,<sup>243</sup> with all units having the same probability of being transfused, appears to have been conservative when compared with SNBTS national statistics for the period 1981–82 to 1993–94. Dr Gillon re-examined this assumption at the request of the Inquiry and concluded that the Scottish percentage should be 66%.<sup>244</sup> That is still less than indicated by available SNBTS national statistics, but Dr Gillon's conclusion is accepted that the variation he found was not statistically significant, and it appears that little turns on this factor.

**3.239** Assumption 8 (a flat profile of the age distribution of recipients of blood transfusion justifying the application of up-to-date data over the whole period),<sup>245</sup> seems consistent with the assumption that the donor population, including IDUs, was homogeneous, but like that general assumption is questionable on the ground of lack of evidence. Return donors seem likely, as a matter of general impression, to have spanned a wider age range than new donors, including injecting drug users. The donor's age at first recruitment does not change, but increases so long as they returns to give blood. However, there are not enough hard data to enable comment on the extent of any differences.

**3.240** It is necessary to be cautious with even these assumptions. Dr Gillon observed that:

[T]he inherent unreliability of this set of assumptions, encapsulating as they do significant numbers of components which could not be traced, would make statistical calculations meaningless.<sup>246</sup>

<sup>245</sup> Schnier and Goldberg, *Estimation of the number of individuals infected and alive as a consequence of blood transfusion in Scotland 1970–1991*, 1 March 2012 [PEN.019.0899] at 0901

<sup>246</sup> Dr Gillon's response to further questions on statistics [PEN.019.1311] at 1312

**3.241** It would be inappropriate to reject statistical exercises generally on that basis. On any view they make a valuable contribution to the overall picture and assist in arriving at an opinion. This observation underlines the need for caution. Having regard to the difficulties with the assumptions in all of the models discussed above, it would be inappropriate to accept the estimates made as conclusive of the extent of transmission of HCV by transfusion.

### General considerations

**3.242** On the evidence available, both expert approaches appear to have followed valid principles of statistical modelling, but each depended on the application of unverifiable and possibly erroneous assumptions, as they freely acknowledged. It is necessary to treat any estimates of prevalence with considerable caution. While it is inevitable that opinions reflecting calculation have to be expressed numerically, it is particularly necessary to avoid being misled by spurious mathematical precision.

**3.243** At the end of the day, all that can be done is to set out a range of estimates which vary depending on the different assumptions made. Professor Goldberg's calculation using a flat rate projection of 0.09% prevalence was worthwhile as indicating a possible maximum number of 6784. It demonstrated the response of his model to the revised assumption, but it was not an assumption for which he offered support. On that basis, the estimate produced by Professor Goldberg's statistical model is that a median number of 1533 patients in Scotland may have been infected with Hepatitis C as a result of blood transfusion between 1970 and the introduction of donor screening in September 1991. Dr Soldan's figure remains 3498 for the period 1980–91.

**3.244** Of the two approaches to the problem in Scotland, Professor Goldberg's approach has the advantage of using more relevant hard data, but remains heavily dependent on assumptions which cannot be objectively verified. Dr Soldan uses less local data, and again her assumptions cannot be verified objectively. Since Dr Soldan was not available as a witness, it was not possible to explore the qualifications expressed in her report.<sup>247</sup> The estimate of 2524 derived from the DoH report falls between the two. As already noted, the methodology adopted in arriving at the figures in the report is not disclosed.

**3.245** So far as Term of Reference 4 is concerned, it is clear (a) that recorded data cannot provide an accurate measurement of the extent of HCV infection in Scotland over the reference period, or of the risk of post-transfusion transmission; and (b) that such statistical models as have been developed to date remain, to a greater or lesser extent, of questionable validity as indicators of total exposure to risk and of transmission. The fundamental problem is that hard data are lacking and assumptions have to substitute for measurement over too wide a range of factors.

### Skipton and other data

**3.246** Professor Goldberg thought the Skipton data to be 'insufficiently robust'<sup>248</sup> and the Inquiry has identified one example in which it is unreliable. However, in the context of so much general uncertainty about other approaches, it has to be considered whether it is for present purposes of assistance in developing an estimate of numbers.

---

<sup>247</sup> Dr Soldan, *Estimated number of individuals infected by blood transfusion in Scotland* [SGH.005.7203]

<sup>248</sup> Letter from Professor Goldberg in response to further queries on statistics from Professor Oliver James [PEN.019.0922]

**3.247** Of the total number of stage 1 payments made by the fund (670) 10 were paid to the estates of people who had died before 2003. Six stage 2 payments were made to a further six estates.<sup>249</sup> Since the 670 included haemophilia patients co-infected with HIV, who had a relatively high mortality, it can reasonably be inferred that there were very few if any payments made to non-bleeding disorder beneficiaries who had died before 2003, and that the number is immaterial for estimating purposes. In any event, on this approach, to assume that all of the additional individuals are transfusion-associated cases is the more conservative approach. Since 2003, there have been deaths among those receiving stage 2 payments: of the 162 stage 2 payments, 37 were known to have died and there were up to 54 possible deaths among the total recipients, with 71 continuing to receive regular payments. The fate of the 54 is unknown, but Mr Fish (the administrator of the Skipton Fund) assumes that many will have died, on the basis that they have ceased to come forward to claim their regular payments. There are no survivorship data for those receiving stage 1 payments only.

**3.248** The number of post-transfusion HCV-infected individuals, estimated on the basis of Skipton data to 1 March 2012 at 439 (paragraph 3.142 above), must have included representatives of individuals who had died. Of the total qualifying recipients (670) at least 24 infected individuals had died. If all of those were assumed to be post-transfusion recipients (the most conservative assumption) there would have been 415 individuals in that group alive in 2012. This number can be contrasted with the finding in the 2011 Goldberg/Schnier model of an estimated median 222 HCV RNA-positive post-transfusion recipients (paragraph 3.192).

**3.249** The Scottish look-back found that 536 (60%) of the 880 recipients of infected components had died by 1995. Since a balance of recipients had not been identified, and Skipton's reference date of 2003 was later, by which time more patients would have died, it can conservatively be estimated from the Skipton non-haemophiliac recipient numbers and using similar mortality data, that a minimum of 1100 patients would have been infected. That is still considerably lower than the DoH figure and the statistically derived figures.

**3.250** The look-back exercise, as devised and implemented, was itself incapable of tracing more recipients than could be associated with the infected donations received after the introduction of screening. A more widely based approach is required to ascertain whether there was support for an estimate based on the DoH exercise.

### Look-back study in Denmark

**3.251** A Danish post-transfusion look-back exercise in 2009 by Just and others, traced the outcome for 960 patients (1018 less 58 untraced after 1996) who prior to 1991 had been exposed to donations from 150 HCV-positive donors.<sup>250</sup> By 1996, 730 had died. Of the 288 alive in 1996, 58 had to be excluded from the study because no personal identification had been supplied and they were untraced. Of the remaining 230, it was found that the pattern of infection was as set out in Table 3.15.

<sup>249</sup> Letter from Nick Fish, Scheme Administrator dated 1 March 2012 [PEN.019.0104]

<sup>250</sup> Just *et al*, 'Long-term follow-up among Danish transfusion recipients identified in the national hepatitis C lookback', *Transfusion*, 2012; 52:582–8 [PEN.018.0507]

**Table 3.15: Danish look-back data**

<b>HCV exposure in 230 Danish patients</b>			
Groups			
Infected individuals: <i>of whom:</i> Patients with cirrhosis Patients who had died	124	23	51
Uninfected individuals: <i>of whom:</i> Patients with cirrhosis Patients who had died	43	3	10
Unknown infection status: <i>of whom:</i> Patients with cirrhosis Patients who had died	63	3	46
Total	230	29	107

**3.252** The number of infected individuals alive in 2009 was 121 (two who left the country during follow-up were excluded) which represented 12.6% of the original cohort of 960 known to have been exposed to blood from HCV-positive donors prior to 1991.

**3.253** If that percentage were applied to the Skipton number of 439, it would indicate a starting cohort of 3484. However, the reference periods are not consistent. Skipton counted patients identified after 2003. Between 2003 and 2009 some of the Danish cohort would have died. There was an observed mortality rate of 4.91%. The deceased members of the cohort over the interval have to be added back to obtain a comparable number at the end of 2003. Assuming five years decrement at 4.91%, the comparable figure for Scotland is 2709, based on the 2003 Skipton numbers and the extrapolated Danish survival data.

**3.254** There are, as always, issues over the reliability of the approach. In relation to the haemophilia population, Danish experience of HTLV-III exposure was compared with experience in Glasgow in a study by Melbye, Froebel and others that is discussed in Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*.<sup>251</sup> In that context, there was a clear distinction in therapy regimes that distinguished the two populations of Denmark and Glasgow. But no other distinctions were noted. Denmark had a well-developed health service and the Danish look-back, which took place at a time after the introduction of screening was very similar to the Scottish exercise. The most significant difference was that the Danish Health Information systems were apparently better organised than those in the UK. Comparison with Denmark provides a further figure, based on a comparable population, that may be used as a control: 2700 would be the number of persons assumed to have been infected in Scotland on this basis, and that is not dissimilar to the results of the DoH exercise (2524 individuals).

<sup>251</sup> See paragraphs 10.7–10.10. Melbye *et al*, 'HTLV-III seropositivity in European haemophiliacs exposed to Factor VIII concentrate imported from the USA', *The Lancet*, December 22–29 1984 [LIT.001.1702]

### *Conclusions on transfusion-transmitted HCV infection*

**3.255** None of the exercises described is capable of producing a firm and reliable estimate of the likely number of NHS patients, transfused in Scotland, who became chronically infected with HCV as a result of receiving infected blood or blood components.

**3.256** Excluding the extremes, a wide range of values remain as indications of the possible incidence of infection. Only a rough and speculative estimate is possible, and the balance suggests a number of around 2500. From Skipton Fund data, extrapolated to 2012, perhaps about 400 of these individuals remained alive in 2012, the last year for which an estimate can be made using available data. A further unknown number of still 'silently' infected individuals probably exists, 23 years after screening began. This number cannot be ascertained reliably. Any attempt to estimate it would be affected by the fundamental lack of hard data reflected in this chapter as a whole. It might be speculated that the number would not be large. But that would involve a dangerous step into unknown territory.

**3.257** Given that throughout most of the earlier years of the reference period it would not have been possible to have measured directly those contracting Hepatitis C from blood transfusion, it would never have been possible through contemporaneous records to arrive at a precise and final figure for those infected, and in particular for those infected and still alive. Estimates supported by statistical analysis would inevitably have been required. Now, even with the best support from expert epidemiologists, it is impossible to use the data available to provide a very satisfactory and reliable number.

**3.258** The work carried out by and for the Inquiry suggests that further epidemiological investigation would not produce a more reliable estimate. Nothing can be done now to improve the contemporaneous records, or to provide hard data indicating objectively the scale of the problem. The reporting system, such as it was, was never designed and operated so as to be likely to be effective, even if it was enforced when means of identifying infected individuals became available. If the Scottish Government is persuaded that, for health policy and strategy, or budgeting or other reasons, it is necessary to develop a more accurate figure, it may be that further research and further expert opinion might eventually converge. That cannot, however, be recommended by this Inquiry given the extensive investigations already carried out.

### *Hepatitis C as a cause of death among transfused patients*

**3.259** Dr Gillon gave evidence that of the 133 patients identified by the HCV look-back exercise who contracted Hepatitis C as a result of transfusion, 49 patients were known to be alive as at January 2011.<sup>252</sup> Information on the recorded causes of death was available for 53 out of the 54 patients known to have died.<sup>253</sup> Dr Gillon's interpretation of data was that Hepatitis C was the cause of death or had made a material contribution to the death of eight of the 53 patients for whom causes of death are known.<sup>254</sup>

**3.260** Professor Goldberg provided evidence that of the 304 individuals recorded by HPS as having contracted Hepatitis C as a result of blood transfusion, 85 individuals were known to be dead as at December 2009 and 219 individuals were not known to be dead

<sup>252</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HCV [PEN.001.0043] at 0047, question 4; Table 8 above

<sup>253</sup> Appendix 3 to Dr Gillon's statement on statistics relating to transfusion-transmitted HCV [PEN.019.1455]

<sup>254</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HCV, [PEN.001.0043] at 0047, question 5 and Day 6, pages 54–58

as at that date.<sup>255</sup> Of the 85 individuals known to have died, 18 had a primary liver-related cause of death recorded on their death certificate, 13 had a secondary liver-related cause of death recorded (including viral hepatitis, liver cancer, alcoholic and non-alcoholic liver disease) and 54 had other causes of death recorded.<sup>256</sup> Professor Goldberg was asked whether a death certificate was a reliable guide to whether an individual had died from Hepatitis C; he replied:

It's not a reliable guide and that's one of the reasons why we use the Hepatitis C diagnosis database in association with the death register, to identify individuals with Hepatitis C who have died, rather than going straight to the death certification register and just relying on the source of that information. It just is completely unreliable in that respect.<sup>257</sup>

**3.261** While the above figures are of some assistance, they require to be treated with caution given that they are based largely on the information contained in each deceased's death certificate which, in turn, depends on the thoroughness and accuracy of the investigation, recording and reporting of each death.

**3.262** The mortality figures spoken to in evidence, both for patients with post-transfusion Hepatitis C and for haemophiliac patients, correlate reasonably well with well-modelled studies from outwith the United Kingdom.<sup>258</sup>

### **Patients with bleeding disorders infected with HIV as a result of treatment with blood products**

**3.263.** The third group of patients to be considered is referred to in paragraph 3.2, item iii, and consists of patients with bleeding disorders, primarily haemophilia, who were exposed to infection with HIV through their treatment with blood products.

**3.264** The Preliminary Report set out the information available to the Inquiry prior to the oral hearings. As with other data, the information has been significantly corrected and updated at and after those hearings.

### ***Evidence of Dr Hay***

**3.265** When Dr Hay first gave oral evidence to the Inquiry on 18 March 2011, it was already understood that the data provided earlier were inaccurate. Dr Hay noted that in retrospect there were not many people thought to have been infected with HIV in 1980: the majority were infected from 1981 through to 1983. The details in the Preliminary Report referred to the date of reporting when a sample had tested positive, not to the date of infection.<sup>259</sup> As a result, the tabulated data were skewed to later dates than the dates of actual transmission, and gave an inaccurate impression of emerging risk.

<sup>259</sup> Dr Hay – Day 8, page 37

**3.266** Further, at that stage Dr Hay's data did not necessarily reflect the numbers of patients who were infected with HIV in Scotland: they showed at best how many patients managed in Scotland were infected with the virus. In a number of cases so managed, HIV infection was first reported by a centre outside Scotland.<sup>260</sup> There were 1382 registered UK patients who were known at May 2010 to have been infected with HIV. Of those, 72 were registered at Scottish centres. Some of the patients registered at English centres had received treatment in Scotland and might have been infected there.<sup>261</sup> Where a patient was managed at more than one centre, identification of the centre at which he was infected was problematic and could involve duplication.<sup>262</sup> There was epidemiological evidence that heavy users of Factor VIII were more likely to contract HIV infection than those using smaller amounts, but that did not assist in determining total numbers likely to have been infected.<sup>263</sup>

**3.267** Before the oral hearings, UKHCDO data had been examined by the organisation and by the Scottish Directors in an attempt to determine how many of the HIV-infected patients registered as managed in Scotland may have been infected at Scottish centres. When Dr Hay first gave evidence, the attempt to reconcile the data from all sources had not been concluded. He thought that without going through each individual's records, it might be impossible to determine exactly where they were when they contracted HIV, and even if that were done, if there were no archived samples it might never be known for certain.<sup>264</sup> At this stage (in 2010) the Scottish Haemophilia Directors were working on UKHCDO data that had yet to be corrected. There was no satisfactory reconciliation.

**3.268** In an effort to resolve the uncertainties and discrepancies in these data, the UKHCDO, led by Dr Hay, and the Scottish Haemophilia Directors, notably Dr Tait (Glasgow) and Professor Ludlam (Edinburgh), conducted a series of data checking and data reconciliation exercises for HIV in parallel with those already described for HCV.

#### *Reconciliation of UKHCDO and Scottish data*

**3.269** It was necessary for there to be a review of all the data available to try to establish reliable numbers. The Directors of the Scottish Haemophilia centres and the UKHCDO examined the data recorded for each patient on the UKHCDO list, to try to determine whether the patient was likely to have become infected with HIV as a result of treatment in Scotland and, if so, at which Scottish centre.

**3.270** A number of issues arose in the comprehensive review that followed of all data available to Scottish Haemophilia centres. There remained the basic problem of double counting of patients. Each centre, operating in isolation, had returned data to the UKHCDO database at Oxford (the National Haemophilia Database) for each patient treated, whether or not the patient was otherwise registered at the centre. For example, a patient registered in Edinburgh who visited Inverness and there received necessary treatment, would be recorded as a separate patient receiving treatment in each centre.<sup>265</sup> For earlier periods, data were returned manually and later entered into the national computer system. It appeared that there had been some transcription errors and other misunderstandings.

---

<sup>260</sup> Ibid page 26

<sup>261</sup> UKHCDO data reproduced in the Preliminary Report at Appendix 1, introduction to Table 3 [PEN.013.1433] at 1458.

<sup>262</sup> Dr Hay – Day 8, page 27

<sup>263</sup> Ibid page 32

<sup>264</sup> Ibid page 26

<sup>265</sup> Professor Ludlam – Day 14, pages 12–13

The Scottish Haemophilia Directors each prepared a methodology to attempt resolution of the problems with the data.<sup>266</sup>

**3.271** The starting point was the tabulated patient-specific data provided by the UKHCDO relating to patients treated in Scotland who were known to have been HIV positive. The data included the dates of the last negative HIV and first positive HIV tests, and the products with which the patient had been treated year by year, including treatment outwith Scotland. In some cases a cause of death was recorded.

**3.272** The UKHCDO data were reviewed at each centre, and some patients were removed from the lists on the basis that they had been HIV positive when they first arrived at a Scottish centre.<sup>267</sup> Professor Ludlam described in some detail the procedure in Edinburgh and south east Scotland. In the Edinburgh Centre alone, identification of patients known to have been positive on first attendance at the centre, served to remove six patients from the original 29 reported by the UKHCDO. Discussions then took place to exclude duplication as between Scottish centres, and in the case of patients treated at more than one centre, to agree at which centre it was most likely that the patient contracted HIV. In cases where there was little or no information available as to the likely date of infection, a judgement required to be made as to the centre at which the patient was likely to have been infected. On review of local records it was found that UKHCDO data included all patients known to the individual centres. Local data were added where available.

**3.273** Professor Ludlam thought it unlikely that there were haemophilia patients in treatment with concentrates who were not registered at a centre. Patients who received treatment outwith a haemophilia centre for a bleeding problem were quickly referred to such a centre, following local laboratory tests.<sup>268</sup> There was a possibility that patients listed by the UKHCDO as English or Welsh patients might have been infected in Scotland if they had been treated in Scotland before moving to England or Wales in the early 1980s. But no such patient was known, and differences in treatment regimes would in any event make it difficult to form a view.<sup>269</sup>

**3.274** After undertaking that exercise the Scottish Haemophilia Directors gave the following evidence as to the number of haemophilia patients infected at their respective centres.

### Royal Infirmary of Edinburgh

**3.275** Professor Ludlam stated that 23 haemophilia patients were infected with HIV as a result of treatment at the Edinburgh centre.<sup>270</sup> All 23 patients had severe Haemophilia A.<sup>271</sup> Eighteen of the 23 patients had received treatment with material from a single batch of SNBTS product (PFC Factor VIII) during the relevant period, and comprised the 'Edinburgh Cohort'.<sup>272</sup> Five patients had received treatment with other SNBTS and commercial products.<sup>273</sup>

<sup>266</sup> For example, Professor Ludlam's statement on the methodology for collation of HIV patients in Edinburgh [PEN.012.0153]

<sup>267</sup> Professor Ludlam – Day 14, pages 34–35

<sup>268</sup> Ibid pages 13–14

<sup>269</sup> Ibid pages 14–15

<sup>270</sup> Professor Ludlam's statement on the methodology for collation of HIV patients in Edinburgh, dated 25 March 2011 [PEN.012.0153], at 0154. See also Dr Tait – Day 14, pages 68–69.

<sup>271</sup> Edinburgh spreadsheet [PEN.019.1461]

<sup>272</sup> Professor Ludlam, Day 14, pages 19–20. The 18 patients forming the Edinburgh Cohort are patients 1–4, 6–15, 17, 18, 20 and 23 on the Edinburgh spreadsheet [PEN.019.1461]. Patients 5, 16, 19, 21 and 22 do not form part of the Edinburgh Cohort.

<sup>273</sup> The commercial products used were all Factor VIII concentrates, namely Cutter 'Koate', Armour 'Factorate' and Immuno 'Kryobulin'.

**3.276** The adjusted list of patients thought to have been infected in Edinburgh was submitted to HPS for any additional information from their register of HIV-infected individuals, including information from death certificates.

**3.277** Routine blood samples from the 1970s were regularly stored by Edinburgh virologists as part of a study of Hepatitis B infection and its transmission in haemophilia.<sup>274</sup> It was therefore possible in many cases to decide retrospectively when the patient had seroconverted to HIV. It was this information that identified as new patients those who were already seropositive when they had arrived in Scotland. This procedure was adopted at all Scottish centres.

**3.278** It was originally thought that all members of the Edinburgh Cohort were infected between March and May 1984 after exposure to a single common batch of Scottish Factor VIII concentrate. Following phylogenetic analysis, there are now thought to have been at least two batches of contaminated Factor VIII responsible for infections in the group. It appears that two or three HIV-infected donors, who were not intravenous drug users or heterosexual males, contributed to the plasma pools.<sup>275</sup>

**3.279** One individual (E22 in the table below) is known to have been infected by Armour Factorate between 16 March and 1 December 1981 (the dates of the last sample testing negative and the first testing positive). One (E16) had samples that tested positive in 1983. One (E19) tested positive in November 1986, having tested negative in January 1985. Two (E17 and E20) were under 16 at the time of their first positive sample.<sup>276</sup> The overall picture is set out in Table 3.16.

**3.280** Four of the 23 patients infected with HIV at the Edinburgh centre were still alive at the time of the oral hearings in 2011 and 19 had died. Of the 19 patients who had died, 14 had either died of HIV/AIDS or HIV/AIDS was a factor contributing to their death.<sup>277</sup> While that information was compiled by Professor Ludlam from information provided by HPS (based on the patient's death certificate) and the UKHCDO database, the latter contained 'very little information' as to the cause of death and more assistance was derived from the information in the death certificates.<sup>278</sup> Professor Ludlam explained that of the five patients whose deaths did not appear to have been caused or aggravated by HIV/AIDS, three deaths were due to a major catastrophic haemorrhage and that one patient clearly

<sup>277</sup> Professor Ludlam – Day 14, pages 22–23, 27–30 and 46–48. Professor Ludlam's statement on the methodology for collation of HIV patients in Edinburgh, dated 25 March 2011 [PEN.012.0153] at 0154

<sup>278</sup> Professor Ludlam – Day 14, pages 44–45

had a condition which was not related to HIV/AIDS at all.<sup>279</sup> Professor Ludlam had the benefit of having been the patients' treating clinician and was able to make an informed judgement on each patient's likely cause of death, rather than having to rely solely on the information recorded in each death certificate.<sup>280</sup>

### Glasgow Royal Infirmary

**3.281** Dr Campbell Tait, Director of the Haemophilia Centre at Glasgow Royal Infirmary (GRI), gave evidence about the results of the exercise in Glasgow.<sup>281</sup> In the final count, 12 patients contracted HIV infection while attending the GRI Haemophilia Centre.<sup>282</sup> Reconciled data are set out in Table 3.17.

**Table 3.17: Glasgow Royal Infirmary HIV infections**<sup>283</sup>

**3.282** Ten of the 12 patients had Haemophilia A (eight severe and two moderate), and two had Haemophilia B (patients G10 and G11). Most of the patients received both commercial products and SNBTS products and it is not always possible to be confident of a robust allocation of imported or PFC products as being the cause of HIV infection. The cause of infection in three cases (G3, G6 and G12) appears clearly to have been the use of imported Factor VIII. Three patients received only PFC Factor VIII between their last negative and first positive HIV test and it appears that these three patients were very probably infected by an SNBTS product.<sup>284</sup> Retrospective testing of stored data, where available, showed that of the 12 patients infected with HIV, one patient seroconverted in 1981–82, two in 1982–83, one between 1982 and 1984, one between 1982–1986, one in 1984–85, one in 1985–86, one during 1985 and, for four patients whose date of last

<sup>279</sup> Ibid pages 46–47

<sup>282</sup> GRI spreadsheet [PEN.019.1456]

<sup>283</sup> Ibid [PEN.019.1456]

<sup>284</sup> GRI spreadsheet [PEN.019.1456] patients 5, 8 and 9. Dr Tait, Day 14, page 63. That was also the opinion of Dr Bruce Cuthbertson on behalf of the SNBTS: Response by Dr Cuthbertson dated 5 June 2011 [PEN.012.1633]. Dr Cuthbertson also considered it likely that patient 10 was infected with HIV from an SNBTS product.

negative HIV test is not known, the first HIV positive tests were, respectively, April 1981, November 1982, May 1984 and November 1985.<sup>285</sup> Ten of the 12 patients infected with HIV were dead by 2011, five from an HIV/AIDS-related cause, one possibly from an HIV/AIDS-related cause, two patients' cause of death appears to have been liver cirrhosis and one patient's death was probably the result of a haemorrhage.<sup>286</sup> Dr Tait's view on the cause of death was based solely on the death certificate codes provided by HPS for each patient.<sup>287</sup> Dr Tait started at the GRI in 1999 and, unlike Professor Ludlam in relation to the Edinburgh patients, had probably not met any of the patients who had died.

**3.283** It is highly likely that the trend of infection from the use of PFC Factor VIII in the GRI was similar to the trend in Edinburgh, namely that these infections were later in time than infections from commercial product. On the evidence available to the Inquiry, heat treatment of Factor VIII from December 1984 eliminated transmission of HIV by SNBTS factor concentrates processed after that date. The distribution of the infections over the period cannot be more precisely estimated.

### Royal Hospital for Sick Children, Yorkhill

**3.284** Dr Elizabeth Chalmers, Director of the Haemophilia Centre at the Royal Hospital for Sick Children (RHSC), Yorkhill, Glasgow, provided evidence that 21 children were infected with HIV as a result of their treatment at RHSC.<sup>288</sup> All 21 children had Haemophilia A (19 had severe haemophilia and two had moderate haemophilia). Imported Factor VIII concentrates were used extensively at the RHSC until 1982,<sup>289</sup> and infections have been identified at earlier periods than elsewhere.

**3.285** All 21 children received both SNBTS product (PFC Factor VIII and cryoprecipitate) and commercial product, in particular 'Factorate' produced by Armour. For 12 of the 21 children, the dates of the last negative and first positive HIV tests are known. Two of the 12 children seroconverted between January 1980 and January 1981, one child seroconverted in 1981, three children seroconverted in 1981–82, four children seroconverted in 1982–83, one child seroconverted between 1981–83 and one child seroconverted between 1982–84.<sup>290</sup> For nine of the 21 children, the date of the last negative test for HIV is not known. The date of the first sample from these nine children to test positive for HIV ranged from September 1982 to May 1985.

**3.286** It appears likely that about five of these 21 children were infected before the first cases of AIDS in haemophilia patients were described in the USA, and that up to 16 were infected before the first case of AIDS in a haemophilia patient was described in the UK.

**3.287** The 21 children were infected with HIV relatively early in the HIV crisis, probably as a result of the widespread use by the RHSC of the commercial product 'Factorate'. Eight of the 21 children infected with HIV have died. Of those eight, five deaths were due to HIV/AIDS, two deaths do not appear to have been due to HIV/AIDS and the cause of one death is unknown.

### Aberdeen Royal Infirmary, Foresterhill

**3.289** Dr Henry Watson, Director of the Aberdeen Haemophilia Centre, provided written evidence that three patients were considered to have acquired HIV as a result of treatment at Aberdeen on the basis that these patients had been treated only at the Aberdeen centre or had received minimal treatment elsewhere.<sup>291</sup> All three patients had Haemophilia A (two with severe haemophilia and one with moderate haemophilia).<sup>292</sup> One patient had been treated only with SNBTS product (PFC Factor VIII and cryoprecipitate) during the relevant period.<sup>293</sup> This patient's last negative test for HIV was 14 July 1983 and he first tested positive for HIV on 18 December 1984.<sup>294</sup> One patient received commercial product

<sup>291</sup> Dr Watson's statement on the methodology for provision of data on HIV infection from Aberdeen haemophilia centre, dated 28 March 2011 [PEN.012.0156]

<sup>292</sup> Aberdeen spreadsheet [PEN.019.1471]. The three patients who were infected with HIV at Aberdeen are patients 1, 2 and 3 on the spreadsheet. See the observations on the spreadsheet by Senior Counsel to the Inquiry, Day 14, pages 2–9.

<sup>293</sup> Aberdeen spreadsheet [PEN.019.1471], patient 3

<sup>294</sup> Report dated 6 April 2011 from Dr Cuthbertson to the Inquiry [PEN.012.1644]

in small amounts in 1978 and 1979 (Baxter 'Hemofil') but otherwise received treatment only with SNBTS product (PFC FVIII and cryoprecipitate).<sup>295</sup> This patient's last negative test for HIV is not known and the patient first tested positive for HIV in January 1985. One patient regularly received commercial product and from time to time received PFC product.<sup>296</sup> Again, this patient's last negative test for HIV is not known and the patient first tested positive for HIV on 1 January 1985. Two of these patients were known to have died. If these patients were infected by Scottish products (which was clearly the position in the first and third cases), all had PFC Factor VIII in 1983 and 1984. Patient A3 is likely to have been infected by the batch implicated in the infection of the Edinburgh Cohort.<sup>297</sup>

### Ninewells Hospital, Dundee

**3.290** Dr Ron Kerr, Director of the Dundee Haemophilia Centre, advised that no haemophilia patients were considered to have been infected with HIV as a result of treatment at Dundee.<sup>298</sup>

### Raigmore Hospital, Inverness

**3.291** Dr Christopher Lush, Director of the Inverness Haemophilia Centre, advised that no haemophilia patients were considered to have been infected with HIV as a result of treatment at Inverness.<sup>299</sup>

### *Results of Scottish Haemophilia Centre Directors' review of UKHCDO data*

**3.292** According to the Directors' evidence, the revised total number of haemophilia patients who contracted HIV while receiving treatment and care at Scottish centres was therefore 59.

**Table 3.19: Total HIV infections**

	Total	Dead	AIDS deaths*	Alive
Royal Infirmary of Edinburgh	23	19	14	4
Glasgow Royal Infirmary	12	10	6	2

Aberdeen Royal Infirmary	3	2	1	1
Total	59	39	26	20

\*This column lists deaths attributable or possibly attributable to AIDS

### *UKHCDO updated report*

**3.293** Following the oral hearings, the UKHCDO undertook further work on its data and provided an updated statistics report.<sup>300</sup> That report listed 73 patients with bleeding disorders first reported to the UKHCDO by Scottish haemophilia centres as testing positive for HIV.<sup>301</sup> The report noted:

<sup>295</sup> Aberdeen spreadsheet [PEN.019.1471], patient 1

<sup>296</sup> Aberdeen spreadsheet [PEN.019.1471], patient 2. This patient received PFC FVIII in 1977, 1978 and 1983 and received Baxter FEIBA between 1979–1983 and again in 1985 (the patient also received Speywood Porcine in 1983, which product is made from pig blood and is not capable of transmitting HIV).

<sup>297</sup> Dr Ludlam – Day 35, page 89; Dr Perry – Day 38, pages 41, 44 and 49 and Dr Cuthbertson – Day 46, page 86.

<sup>298</sup> Letter from Dr Kerr to Tracey Turnbull, dated 1 February 2010 [PEN.001.0234]

<sup>299</sup> Letter from Dr Lush to Tracey Turnbull, dated 31 January 2011 [PEN.001.0235]

<sup>300</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012 [PEN.019.0927]

<sup>301</sup> Ibid page 29 [PEN.019.0927] at 0961

Scotland accounts for about 10% of the UK haemophilia population but only about 5% of the patients with bleeding disorders infected with HIV. 1383 patients with bleeding disorders are known to have been infected with HIV in the UK and were reported to NHD, of whom 73 were first reported to NHD by Scottish Centres.

**3.294** Of the 73 patients who tested positive for HIV, 29 were reported from the Edinburgh centre, 24 from Glasgow Royal Infirmary, 11 from the RHSC, Glasgow, seven from Aberdeen, two from Inverness and none from Dundee.<sup>302</sup>

**3.295** The UKHCDO then analysed all of the data available on the National Haemophilia Database (NHD) to determine (a) which patients in the list of 73 were probably not infected in Scotland; and (b) which patients first reported to NHD by centres outwith Scotland were probably infected in Scotland. Five patients were probably infected outwith Scotland. The position of one additional patient was unclear: he was a severe Haemophilia B patient who had been treated extensively in Scotland and England in the nine months within which he seroconverted, with a variety of NHS and commercial products. Detailed analysis of the records of patients in the second group identified one patient who was probably infected in Scotland and two more who might have been infected either in Scotland or in England, where the data indicate treatment in both countries at critical periods but could not identify a single place where infection probably occurred.

**3.296** According to the UKHCDO, at that stage the range of patients probably infected in Scotland, taking account of the uncertain cases, was therefore 68–70.<sup>303</sup>

#### *HPS HIV Diagnosis Database*

**3.297** Professor Goldberg gave evidence that following the development of an HIV antibody test in 1985, HPS (then known as the Communicable Diseases (Scotland) Unit) established an HIV Diagnosis Database for Scotland.<sup>304</sup> The database holds data on all individuals diagnosed HIV antibody positive in Scotland and individuals previously diagnosed outside Scotland who came to reside in Scotland. Since 1989 a standardised National HIV Test Request Form has been used by laboratories; the form is made available to clinicians in clinical settings, allowing relevant information to be recorded by the clinician at the time of blood sampling.

**3.298** In a letter dated 23 March 2011 from HPS to the NHS Scotland Central Legal Office, it was stated that, 'As at 31 December 2010, HPS had recorded 46 deaths among 76 haemophiliac cases who are presumed to have been infected via the receipt of contaminated blood products in Scotland'.<sup>305</sup>

#### *Further investigation*

**3.299** Discrepancies in the numbers of patients considered likely to have become infected with HIV as a result of treatment in Scotland for blood coagulation disorders, prompted a request to Dr Hay and Professor Ludlam to explain the differences and, if possible, to reconcile the data. They carried out a further exercise and on 27 February 2013 produced a

<sup>302</sup> Ibid pages 34–35, table 3 [PEN.019.0927] at 0966 and 0967

<sup>303</sup> 73 less 5 clear and 1 possible cases plus 1 clear additional case = 68; 68 plus the two possible additional cases = 70.

<sup>304</sup> Professor Goldberg's statement on statistics relating to haemophilia patients infected with HCV, dated 1 February 2011 [PEN.001.0206] at 0210

<sup>305</sup> Letter from Glenn Codere, HPS, to Tracey Turnbull, CLO [PEN.012.0151]

short report that dealt comprehensively with the main questions posed.<sup>306</sup> Professor Lowe and Dr Tait (Glasgow) and Dr Watson (Aberdeen), along with staff of the UK National Haemophilia Database (NHD) were involved in the collaboration.

**3.300** Using patient data held locally, including details not recorded in the NHD, and the NHD data for treatments at centres other than those at which the patient was registered, enabled an accurate estimate to be made of the time each patient contracted HIV and the centre which administered the treatment responsible for the infection. In the course of the work of reviewing the records, a Scottish patient was identified who had not been registered or treated at any Scottish Haemophilia Centre but had probably been infected by treatment at a non-specialist Scottish Centre. It was concluded that this patient should be added to the Scottish Haemophilia Directors' previous total of 59, giving a new total of 60.

**3.301** All 59 members of the Scottish Haemophilia Directors' initial group were included in the NHD data. The total number derived from preliminary review of the NHD as probably or likely to have been infected in Scotland was 74, one more than published in the report of April 2012. On detailed analysis of the treatment records and HIV blood test results of the patients, it was found that three patients were probably infected in England. Ten patients who had arrived in Scotland from abroad, and were registered directly at Scottish Haemophilia Centres, were shown to have been HIV positive when they arrived. One further patient from abroad was found to be anti-HIV negative on arrival in Scotland, but HIV positive shortly thereafter. On review of his treatment records it was concluded that he had been infected before arrival, but was in the 'window period' following infection, before antibodies were detectable, 'incubating' the disease on arrival. That was thought to fit better with the known incubation period of HIV than the alternative, which would have required infection immediately on arrival in Scotland, and an unusually short incubation time.

**3.302** The result was that NHD data were fully reconciled with the SNBTS Haemophilia Directors' data. Sixty patients with bleeding disorders were infected with HIV in Scotland by treatment in Scotland.

**3.303** The results from the collaborative investigation carried out by the Scottish Haemophilia Directors and Dr Hay with the cooperation of the UKHCDO are accepted as accurate. Health Protection Scotland's data are an accurate reflection of the information collected. However, the patients notified to HPS were those with a positive HIV test who were classified on the request form submitted to the virology laboratory in Scotland as either having haemophilia or having been a recipient of a clotting factor concentrate. HPS does not have access to information about where patients were likely to have acquired HIV infection. As a result, some data are likely to relate to individuals infected outwith Scotland who subsequently were tested in Scotland. The need to adjust the UKHCDO data for this factor demonstrates that it may be sufficiently significant in itself to undermine the reliability of the HPS numbers for present purposes. Overall however, the investigations carried out by Dr Hay, Professor Ludlam and others have now been sufficiently specific and detailed to make the outcome preferable to inferences drawn from HPS data.

---

<sup>306</sup> Dr Hay and Professor Ludlam's joint response, dated February 2013 [PEN.019.1328]

**3.304** Not all deaths due to AIDS were registered as such, and reporting of the condition while patients were alive may also have been less than complete because of the stigma associated with HIV infection and the AIDS complex of diseases. The detailed work undertaken in the course of the collaborative exercise underlines the difficulty in arriving at any conclusive view on the actual prevalence of HIV infection, even in a closely monitored cohort such as haemophilia patients, given the lack of precise information on some individual patients' cases. Although the figure of 60 may not be absolutely accurate it is unlikely that more precise figures will ever be established than those available from the collaborative exercise.

#### ***Source of infection – SNBTS or commercial product***

**3.305** Dr Bruce Cuthbertson gave evidence that the SNBTS considered it likely that in total 25 patients were infected as a result of treatment with SNBTS products (comprising 19 patients in Edinburgh, four patients at Glasgow Royal Infirmary and two patients in Aberdeen).<sup>307</sup>

**3.306** While in many cases it is difficult to identify the particular product that infected a patient with HIV, it appears in general that commercial blood products carried a greater risk of transmission of HIV than products produced by the SNBTS from plasma from Scottish blood donors.

**3.307** Dr Cuthbertson said:

For those who were known to have received both SNBTS and commercial products, the assignment of probability [as to the source of infection] will partly be determined by date of first detection of antibody to HIV and the date of the last negative HIV test result. For those patients who received both products within a time period consistent with HIV infection, it is more likely that the source of infection was the commercial product. This supposition is based on SNBTS current understanding of the frequency of HIV transmission by commercial and NHS products at that time, and is further supported by the much lower HIV infection rate in Scotland when compared with those haemophilia populations which were treated exclusively with commercial FVIII of US manufacture .... This difference is found in many publications, including that from Moffat, Bloom and Mortimer, 1985 (*Lancet* 1, p935)<sup>308</sup> who found a significant difference ... between the infection rate in patients treated with US FVIII concentrate and those treated with UK concentrate. Similarly, Kroner et al, 1994 (*J. Acquired Immune Deficiency Syndromes*, 7:279–286) reported that more than 90% of moderate and severe haemophiliacs treated with American product seroconverted to HIV.<sup>309</sup>

**3.308** While it does appear that there is support for the assumption relied on in allocating contentious cases, it has to be observed that the Scottish product was infectious in some cases, and, as the UKHCDO April 2012 report shows, allocation can still be problematic. Dr Cuthbertson's evidence is accepted, but with a note of caution: so far as it is based on assumption it is not wholly based on hard data and cannot be accepted as absolutely accurate.

<sup>307</sup> Report dated 5 June 2011 from Dr Cuthbertson to the Inquiry [PEN.012.1633]

<sup>308</sup> Moffat et al, 'HTLV-III antibody status and immunological abnormalities in haemophilic patients', *The Lancet*, April 20, 1985 [PEN.016.0432]

<sup>309</sup> Report dated 5 June 2011 from Dr Cuthbertson to the Inquiry [PEN.012.1633]

**3.309** The updated UKHCDO statistics report notes that Scotland accounts for about 10% of the UK haemophilia population but only about 5% of patients with bleeding disorders in the UK infected with HIV.<sup>310</sup> In the updated report Dr Hay observed:

The relatively low proportion of Scottish patients infected with HIV reflects the fact that Scotland was more self-sufficient in blood and blood products from PFC than England during the period of risk. BPL fractionated most of England's requirement for factor IX but only approximately 40% of England's requirement for factor VIII. England was therefore far more dependent on imported factor VIII concentrates than Scotland. These imported products were largely manufactured from US-sourced plasma and plasma obtained from various other countries, including Africa. HIV spread earlier through the US and African donor population than the UK donor population and so patients using commercial products had a much higher risk of contracting HIV, especially early in the HIV epidemic in 1980, 1981 and 1982. Where English patients were maintained on a single brand of concentrate during the period of risk the risk of contracting HIV was much higher (approaching 100% in some centres) in those patients using US-sourced concentrates.<sup>311</sup>

**3.310** Newcastle and Liverpool were centres in that last category. Referring mainly to severely affected patients, Dr Hay explained:

In some centres, including the one that I worked in as a junior doctor, people were kept on one brand of concentrate as long as possible. It was felt that that might minimise their chance of contracting non-A non-B hepatitis. In fact, that proved to be completely false. It didn't really matter which concentrate they got from that perspective but it did provide us with evidence that those that just used English Factor VIII had approximately half the incidence of HIV observed in the group treated with commercial concentrates. I think that that was largely because HIV spread earlier into the US donor population than into the UK donor population. Of course, there may have been differences in the donor population between Scotland and England.<sup>312</sup>

**3.311** That there was a greater risk of HIV from commercial concentrates appears to be illustrated by the respective incidence of HIV infection in the Scottish centres.

**3.312** From the figures supplied by the Scottish Haemophilia Directors, all but two of the 59 patients with haemophilia identified by them as infected with HIV as a result of treatment at a Scottish centre, had Haemophilia A. Approximately five per cent of patients with Haemophilia A registered at GRI were infected with HIV as a result of their treatment at that centre (10/211).<sup>313</sup> Similarly, approximately 5% of patients with Haemophilia A registered at Aberdeen were infected with HIV as a result of their treatment at that centre (3/60). No haemophilia patients were considered to have been infected with HIV as a result of their treatment at the Dundee or Inverness centres.

<sup>310</sup> 1383 patients with bleeding disorders are known to have been infected with HIV in the UK, of whom 73 were first reported to the UKHCDO by Scottish centres: UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012, [PEN.019.0927] at 0961

<sup>311</sup> *Ibid* page 33 [PEN.019.0927] at 0965

<sup>312</sup> Dr Hay – Day 8, page 31

<sup>313</sup> The numbers of patients with each type of bleeding disorder registered at each Scottish haemophilia centre at five yearly intervals between 1970 and 2011 are provided in the UKHCDO updated report, April 2012, table 2. The registered patients at each Scottish centre in 1985 are shown at page 25 of the updated report.

In the early 1980s all of these centres used primarily SNBTS rather than commercial products.<sup>314</sup>

**3.313** The Edinburgh Centre used mainly SNBTS products in the early 1980s. While there was a greater incidence of HIV at the Edinburgh Centre compared with the other adult centres in Scotland (approximately 13% (23/172) of patients with Haemophilia A registered at Edinburgh in 1985 were infected with HIV as a result of their treatment at that centre) it appears, as discussed above, that 18 of the 23 patients infected at Edinburgh were infected by a small number of batches of SNBTS/PFC Factor VIII. Infection by these batches of concentrate made up about 38% of the total number of Scottish infections.

**3.314** In contrast, the greatest user of commercial concentrate in the Scottish centres in the early 1980s was RHSC Yorkhill, where almost 30% of the children with Haemophilia A registered at that centre in 1985 were infected with HIV (21/73).

**3.315** In conclusion, in Scotland, as was the case elsewhere, commercial concentrates produced by US companies appear to have carried the greatest risk of transmitting HIV.

#### *HIV – Secondary transmission*

**3.316** As noted in this Report at Chapter 8, *Knowledge of HIV/AIDS Now*, paragraph 8.24, secondary transmission of HIV is a real risk, whether from mother to baby or as a result of sexual contact, though reported numbers are small. Professor Ludlam advised that he was not aware of any partners of HIV positive haemophilia patients who became infected with HIV.<sup>315</sup> Dr Tait advised that to the recollection of staff in Edinburgh and Glasgow, no partners of haemophilia patients were HIV positive, albeit there were limited data in that regard.<sup>316</sup> Dr Henry Watson, at Aberdeen, stated that there were no accurate data relating to HIV infection in the partners of infected patients.<sup>317</sup> Beyond noting that some patients who contracted HIV as a result of infected blood or blood products may have inadvertently infected others, it is not possible for the Inquiry to make precise findings or estimates in that regard.

#### *HIV as cause of death*

**3.317** As noted at paragraph 3.302 above, 60 patients with bleeding disorders were infected with HIV in Scotland by treatment in Scotland. Examination of the histories of 59 of those patients, reported in Table 3.19 above, showed that 26 had died of AIDS-related causes. The remaining patient was also recorded as having died of AIDS.<sup>318</sup> Thus, of the 60 patients infected by treatment in Scotland, 27 died of AIDS-related causes.

**3.318** This figure does not represent the total number of deaths from AIDS-related causes among patients in Scotland with bleeding disorders. Figures from the UKHCDO of 48 deaths<sup>319</sup> and from HPS of 46 deaths<sup>320</sup> include cases where the patient's HIV infection was acquired from treatment outwith Scotland.

<sup>314</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012, pages 3–23, table 1 [PEN.019.0927] at 0935–0955.

<sup>315</sup> Professor Ludlam's statement on the methodology for collation of HIV patients in Edinburgh, dated 25 March 2011, [PEN.012.0153] and Day 14, page 16

<sup>319</sup> UKHCDO report *National Haemophilia Database: Bleeding disorder statistics for the Penrose Inquiry*, 2012, page 54, table 9 [PEN.019.0927] at 0986

<sup>320</sup> Letter from Glenn Codere, HPS, to Tracey Turnbull, CLO [PEN.012.0151]

**3.319** The recent data provided by the UKHCDO do not include direct data on the patients registered with Scottish haemophilia centres who died of HIV. The data do, however, disclose that of 158 patients with Haemophilia A treated at Scottish Haemophilia Centres and who died between 1969 and 2011, 48 patients died of HIV (ie just over 30%).

**3.320** In addition, as noted at paragraph 3.298 above, HPS noted that, as at 31 December 2010, they had recorded 46 deaths among 76 people with haemophilia assumed to have been infected through blood products in Scotland.

**3.321** The pattern of deaths among HIV-infected patients shown in Table 3.19 above illustrates the relative mortality risks among patients who were young or old at the time of infection. Patients at RHSC, Glasgow have a significantly better survival record historically and, having survived into the era of effective treatment, a much better prognosis and life expectancy than patients who were older at the date of infection.

### **Patients infected with HIV as a result of blood transfusion**

**3.322** The fourth group of patients to be considered is referred to in paragraph 3.2, item iv, and consists of patients who were exposed to infection with HIV through transfusion with blood or blood components.

**3.323** An HIV look-back exercise started in 1985 as a UK-wide initiative of the Health Protection Agency.<sup>321</sup> The Blood Transfusion Services in England, Wales and Scotland agreed to participate when assured that the data would be sufficiently anonymised for no patient to be identified through it, and that the data would remain available to clinicians throughout the United Kingdom for research.<sup>322</sup>

**3.324** From the date of formal commencement of routine testing (15 October 1985) the look-back exercise traced the fate of all blood components from donations made during the preceding five years, by donors who were after that date found to be anti-HIV positive on returning to make a repeat donation. From a starting point of 39 anti-HIV positive donors with a history of previous donation, this process identified 10 anti-HIV positive patients in Scotland. In addition the SNBTS had information from the sporadic reports of clinicians, about patients with HIV infection where the sole risk factor was transfusion.

---

<sup>321</sup> Dr Gillon – Day 6, page 59

<sup>322</sup> Ibid page 71

**3.325** The data for infected donors in Scotland are shown in bar form in Figure 3.6.

**Figure 3.6: HIV-infected blood donations: Scotland**

**3.326** The 39 anti-HIV positive return donors represented the numbers presenting at donor sessions between October 1985 and the end of 1997. Fourteen return donors were found to be HIV-positive between 1998 and 2009. The look-back exercise targeted the period when the highest concentrations of infected return donors presented and were tested, but it was not comprehensive. Return donors who continued to appear and test positive after the reference period for the look-back study were not included. While the possibility of additional return donors since 2009 appears remote, the inclusion of any who did appear might have led to identification of additional patients who received infected components. It is not possible, however, to deduce from these data the numbers of possible return donations after 2009.

**3.327** A further difficulty that arose with the look-back exercise was that comprehensive archive samples were not available for the whole period of risk of transmission of HIV. Systematic storage of archive samples began in Edinburgh in mid-1984 and in Glasgow in 1986.<sup>323</sup> In the circumstances, reliable information on numbers of infected donations was available from about 1985.

**3.328** There was a supplementary source of data in returns from virology laboratories to HPS. As already noted at paragraph 3.297, in 1985 HPS (formerly SCIEH) put in place a reporting system throughout Scotland. The system used a single unified referral form for clinicians' use in requesting virology laboratories to carry out an HIV test. SCIEH automatically received a copy of the referral form for every test that proved positive. From that time, every transfusion patient testing positive for HIV at a Scottish virology laboratory was reported.<sup>324</sup> But the data were anonymised, limiting the scope for further

<sup>323</sup> Ibid page 60

<sup>324</sup> Ibid pages 9–10; Professor Goldberg – Day 6, page 147

investigation.<sup>325</sup> In 1985, the virus had only been present in the general population, and therefore by inference in the donor population, for about five years. When the test was introduced, the number of potentially dangerous previous donations from any individual donor was limited to that period.<sup>326</sup> So far as available, the data were reflected in the final figures presented by the SNBTS/HPS.

**3.329** As a result of concerns about the published information, all available data were reviewed for the Inquiry with a view to developing a more reliable picture of the information collected. The evidence was presented by Dr Gillon on behalf of the SNBTS and HPS. In total 18 patients are known to have contracted HIV infection as a result of blood transfusion in Scotland.<sup>327</sup> Ten of these patients were identified through the targeted look-back exercise by the SNBTS following the introduction of HIV screening in October 1985. Eight patients were reported by their clinicians, independently of the look-back exercise, as possible transfusion-transmitted infections. In four of these eight cases it was possible to identify an HIV positive blood donor as the likely source of infection. Of the remaining four, a circumstantial connection was established in three cases, but it was not possible to establish a date of transfusion. Each of the three patients had received more than one transfusion, transfusion had occurred before testing for HIV had begun, and there were no archived samples. But the patient had no other likely source of infection.<sup>328</sup> The remaining patient was reported to SCIEH by clinical staff at the Western Infirmary, Glasgow, but was not known to the SNBTS.<sup>329</sup>

**3.330** After further research, Dr Gillon provided a table showing information on probable dates of infection for all 18 patients.<sup>330</sup>

**3.331** In chronological order, the dates of transfusion of HIV-infected blood or blood components in these patients are shown in Table 3.20. These data represent the best information available to the SNBTS.

<sup>328</sup> Dr Gillon – Day 6, pages 58–59 and Witness Statement [PEN.001.0038]

<sup>329</sup> Dr Gillon's statement on statistics relating to transfusion-transmitted HIV, dated 31 January 2011 [PEN.001.0038] and Day 6, Page 58

<sup>330</sup> *Ibid* [PEN.001.0038] at 0039 and 0042

**Table 3.20: Transfusion-transmitted HIV infection: dates of transfusion**

Patient	Date of transfusion	Annual total
1	13 August 1983	
7	31 December 1983	
2	1983 or 1984	1983:2/3
6	11 January 1984	
8	January 1984	
4	March 1984	
3	April 1984	
14	25 April 1984	
13	'early' 1984	
12	Before June 1984	
10	9 June 1984	
15	September 1984	
17	30 October 1984	
5	November 1984	
9	1984	1984:12/13
16	September 1985	1985:1
11	August 1986	
18	August 1986	1986:2

**3.332** For two patients, infective transfusion in August 1986, well after HIV screening of donors had been introduced, tends to confirm that the early anti-HIV tests were not 100% reliable in detecting infected donors.<sup>331</sup> In particular, as antibody tests, they could not detect infection during the window period following infection and before antibodies were produced.

**3.333** Eight patients were infected in Lothian, six in Greater Glasgow, three in Tayside and one in Lanarkshire health board areas. The distribution by Regional Transfusion Service was:

- Edinburgh and south east: eight
- Glasgow and west of Scotland: seven
- Dundee and Tayside: three.<sup>332</sup>

Neither of the other two regions, Highlands and Grampian, had any cases of transfusion-transmitted HIV/AIDS.<sup>333</sup>

<sup>331</sup> Ibid [PEN.001.0038] at 0042

<sup>332</sup> Ibid [PEN.001.0038]

<sup>333</sup> Dr Gillon – Day 6, page 65

**3.334** The most critical years for confirmed infection were 1983 and 1984, a factor that will become significant when the date of introduction of testing is considered. It will also be significant that the first nine months of 1985 saw one case only of transfusion-transmitted HIV infection.

**3.335** Fifteen of the 18 patients were known to have died as at 31 December 2010. The causes of death were not known, but Dr Gillon commented that, based on HPS data, many of these patients will have died of AIDS.<sup>334</sup>

**3.336** The figure of 18 patients known to have contracted HIV as a result of blood transfusion in Scotland is probably an underestimate. The actual incidence of HIV in Scottish donors between the assumed arrival of the HIV virus in the Scottish blood supply (around 1982) and the commencement of HIV screening of donors (October 1985) is not known. On general grounds, a significant (though not necessarily large) number of individuals infected with HIV by transfusion probably died of the underlying illness for which they were treated, or from other unrelated causes (such as the diseases associated with advancing age), before AIDS-related symptoms appeared. Similarly, an inherent problem of look-back is that some donors may have made HIV-infected donations before October 1985 but not presented to make further donations after the commencement of the exercise. The possible number of patients infected by such donors is likely to have been small, yet it remains unknown.

**3.337** On the other hand, it is unlikely that there were more than a very few post-transfusion AIDS or AIDS-related deaths which remained unidentified among those who survived the typical asymptomatic post infection period. AIDS and the AIDS-related complex present as very serious, usually fatal, illnesses once they develop, and it is highly likely that almost every Scottish AIDS case will have had a cause attributed to it: eight of the 18 known cases were reported by clinicians.

**3.338** The Preliminary Report included, at appendix 4, a table from the SCIEH (now HPS), showing the cumulative total, of AIDS cases as at 30 September 1999, AIDS deaths and HIV-infected persons registered or reported in Scotland. The table indicated that there were 33 recipients of blood or blood products recorded as being HIV positive, 18 male and 15 female. For the purposes of the table, 'blood product' does not appear to include blood products prescribed to haemophilia patients (e.g. clotting factor concentrate), as haemophilia patients are shown separately in the table. While not all of these 33 individuals necessarily received the infective blood transfusion in Scotland,<sup>335</sup> the record does perhaps suggest that the figure of 18 patients discussed above may be a little low, albeit the true figure will not be as high as 33. The HPS figure included patients who might have been infected outside Scotland.

**3.339** It is not possible to be more precise on the evidence available.

### Co-infection with HIV and Hepatitis C

**3.340** It is not known whether any of the 18 patients known to have been infected with HIV as a result of blood transfusion in Scotland were also infected with Hepatitis C.<sup>336</sup>

<sup>334</sup> Ibid page 66

<sup>335</sup> Note 1 to the table notes that, 'Some cases have arisen from transmission which occurred outwith the UK'.

<sup>336</sup> Dr Gillon – Day 6, pages 77–79

**3.341** It is likely, however, that all haemophilia patients who contracted HIV as a result of treatment with blood products made from large pools of plasma also contracted Hepatitis C. Dr Tait stated:

As we know, unfortunately some of the HIV patients would have died before Hepatitis C testing became available but I think it's a fairly reasonable assumption that virtually all HIV positive patients would also have been Hepatitis C positive.<sup>337</sup>

### Summary of conclusions

- Generally, contemporaneous records, whether of patients exposed to risk or of the incidence of infection, were either not maintained at all or were or have become over time, incomplete and unreliable.
- In the case of each of HIV/AIDS and HCV, there was a period when the agent of transmission was not identified, and no reliable diagnostic tests were available, and when effective recording of comprehensive data on the incidence of disease would therefore have been impossible.
- The Public Health (Infectious Diseases) (Scotland) Regulations 1975 did not achieve the reporting of viral hepatitis, pre-dated any requirement for the reporting of HIV and in any event were never enforced.
- Throughout the period when transmission of the index infections by blood, blood components and blood products exposed NHS patients to risk, there were no regulatory or other administrative systems capable of recording and monitoring the numbers of NHS patients in Scotland treated with blood and blood products, or the numbers exposed to risk of infection with the Hepatitis C virus and HIV, or the numbers contracting either or both such infections as a consequence of such treatment.
- The Blood Safety and Quality Regulations 2005 and the Public Health etc. (Scotland) Act 2008 have provided a statutory framework for improved reporting and recording of infection, and should be effective provided they are enforced and are supported by appropriate procedural rules.
- So far as patients with blood disorders are concerned, the National Haemophilia Database maintained by the UKHCDO and the records of individual haemophilia centres, as now adjusted, have provided the best evidence. However, due to anonymisation and reliance on voluntary compliance with requests for information and reporting, the records may not have yielded comprehensive information relating to infection and the consequences of infection for NHS patients.
- In the case of each of the index infections, the data extracted from records of known or recorded cases of transfusion-transmitted virus infection represent minimum numbers of patients who were infected. They probably do not reflect the actual number of patients who are likely to have contracted the disease in that way.
- So far as Term of Reference 4 is concerned, it is clear that recorded data cannot provide an accurate measurement of the extent of HCV or HIV infection in Scotland over the reference period, or of the risk of transmission of infection.

<sup>337</sup> Dr Tait – Day 14, page 132

- None of the statistical analyses carried out provided a single reliable source of information. A sensitivity analysis was not carried out to test the assumptions made in varying conditions. Such statistical models as have been developed to date remain of doubtful validity as indicators of total exposure to risk and of transmission. The fundamental problem is that hard data are lacking and assumptions have to substitute for measurement over too wide a range of factors.
- The work carried out by and for the Inquiry suggests that further epidemiological investigation would not produce a more reliable estimate, at least without disproportionate expense. Nothing can be done now to improve the contemporaneous records, or to provide hard data indicating objectively the scale of the problem. The reporting system, such as it was, was never designed and assembled so as to be likely to be effective even if enforced. If the Scottish Government is persuaded that, for health policy and strategy, or budgeting or other reasons, it is necessary to develop a more accurate figure, it may be that further research and further expert opinion might eventually converge. That cannot be recommended by this Inquiry.
- Excluding the extremes, a wide range of values remain as indications of the possible incidence of infection. Only a rough and speculative estimate is possible, as set out in Table 3.21.

**Table 3.21: Estimated numbers of NHS patients infected and outcomes**

Infection	Estimated number infected	Estimated number of deaths from liver-related causes (HCV infection) or AIDS (HIV infection)
Bleeding disorder HCV	478 <sup>338</sup>	Unknown overall: 21 to 30 deaths reported from various studies <sup>339</sup>
Transfusion-transmitted HCV	Around 2,500 <sup>340</sup>	Unknown overall: 8 of 133, per Dr Gillon; 31 of 304 per Professor Goldberg <sup>341</sup>
Bleeding disorder HIV	60 <sup>342</sup>	27 AIDS or AIDS-related deaths <sup>343</sup>
Transfusion-transmitted HIV/AIDS	18 minimum <sup>344</sup>	Up to 15 <sup>345</sup>

**3.342** Whatever the exact number of cases of transfusion-transmitted HCV might be, there are individuals currently infected with HCV as a result of blood transfusion who may not have been diagnosed. This topic is taken up in Chapter 35, *An Investigation into the Steps Taken to Identify the Individuals who were Infected (Look-back)*. The question of further investigations to identify these patients is discussed there. Any data recovered would incidentally have a bearing on the statistics. The primary focus should clearly be on identifying those who may benefit from treatment and who, despite previous attempts to identify them, remain unknown to the NHS.

## CHAPTER 4

### EXPERIENCES OF THE PATIENTS AND THEIR FAMILIES – WITNESS STATEMENTS

#### Introduction

#### 4.1 Term of Reference 10 requires the Inquiry:

To examine any particular adverse consequences for patients treated by the NHS in Scotland and their families of infection through blood and blood products with Hepatitis C and HIV, including the treatment offered.

This chapter and the following two chapters will explore the evidence available to the Inquiry from patients and their families about their experiences of the infections and of the impact of these on their lives.

**4.2** At the stage of preparation of the Preliminary Report, published in 2010, many patients who had acquired either or both HIV and Hepatitis C infection from blood or blood products, and their relatives, had provided written statements to the Inquiry. Details of how these witness statements were taken are narrated in paragraphs 4.18–4.23 of the Preliminary Report. Seventy-eight witness statements were finalised prior to the publication of the Preliminary Report and these witness statements alone provided the basis for Chapter 4. Since publication, further witness statements have been obtained by the Inquiry. In total the Inquiry has taken statements from 159 patients and relatives relevant to the reference period.<sup>1</sup>

**4.3** From these 159 patients and relatives, the Inquiry selected six witnesses to give oral evidence in respect of the effects of infection with HIV, including the effects of treatment, on patients and their families,<sup>2</sup> and seven witnesses to give oral evidence in respect of the effects of infection with Hepatitis C, including the effects of treatment, on patients and their families.<sup>3</sup> The evidence relating to these thirteen witnesses is dealt with in detail in the two chapters that follow this one. The approach used to select these witnesses is narrated in Appendix 1, *Inquiry Procedures*.

**4.4** What follows is a summary of the remaining witness statements (excluding the witness statements of the 13 witnesses who gave oral evidence and their 11 relatives) consisting of the witness statements of 90 patients and 45 relatives. Certain issues were raised by witnesses in the original 78 statements and referred to in Chapter 4 of the Preliminary Report, namely: the information given to patients (or their parents) about the risk of AIDS and about the risk of non-A, non-B Hepatitis, before their treatment with blood or blood products; the tracing and testing of patients who might have been exposed to the viruses through their treatment with blood or blood products; and the information given to patients who might have been infected, or who were found to be infected, and their families. During the oral hearings these issues were explored in evidence as part of the Topics B5 and C5 and the outcome of this is detailed in Chapters

<sup>1</sup> This figure excludes the witness statements taken from the relatives of those whose deaths were specifically referred to the Inquiry under Term of Reference 6. See Chapter 7, *An Investigation into the deaths of the Reverend David Black, Mrs Eileen O'Hara, Mr Alexander Black Laing, and Mr Victor Tamburrini*.

<sup>2</sup> See Chapter 5, *An Examination of the Effects of Infection with HIV on Patients and their Families, Including Treatment*.

<sup>3</sup> See Chapter 6, *An Examination of the Effects of Infection with Hepatitis C on the Patients and their Families, Including Treatment*.

33 and 34.<sup>4</sup> This summary of the witness statements does not rehearse these points but it focuses, in particular, on Term of Reference 10.

**4.5** It is not appropriate to weigh individual witnesses' evidence on too fine a scale. Inevitably, some specific accounts might fail to persuade one of the reliability of the evidence on particular points of detail. Taken as a whole, however, the cumulative impression from the evidence is that it has a high degree of coherence and consistency and provides great confidence in its overall reliability. It paints a distressing picture of seriously debilitating and sometimes fatal illness that makes its own impact without further comment in this Report.

**4.6** It should not be inferred, however, that every patient infected with either virus has experienced or will experience all of the consequences described. In some cases the diseases have been relatively benign and for some patients infection has been asymptomatic. Treatment is now available that can deal with many of the consequences described, though with side-effects that can themselves be distressing and difficult to manage on an individual basis. Inevitably those who have come forward are individuals with an account of the impact of infection that they wish to describe. Relatively few are motivated to come forward and explain that they have not been affected, or affected to any material extent, by infection. The evidence described is eloquent of what does happen, and what can happen. It does not provide a forecast of what will inevitably happen in every case.

## The witnesses

### 4.7 Table 4.1: Summary of the 90 patient witness statements

Means of infection	Witness infected with Hepatitis C	Witness infected with both HIV and Hepatitis C	Total number of witnesses
Treatment for Haemophilia A	19	2	21
Treatment for Haemophilia B	7		7
Treatment for other blood disorders, i.e. von Willebrand disease and Platelet Storage Pool Deficiency	6		6
Blood transfusion	50		50
Treatment with Immunoglobulin and Anti-Rh antibodies	2		2
Secondary infection	4		4
<b>Total</b>	<b>88</b>	<b>2</b>	<b>90</b>

**4.8** The Inquiry is aware that several patient witnesses who provided statements have since, sadly, died.

<sup>4</sup> Topic B5a) The information given to patients (or their parents) about the risk of AIDS before their treatment with blood or blood products; b) the tracing and testing of patients who might have been exposed to the virus through their treatment with blood or blood products; and c) the information given to patients who might have been infected, or who were found to be infected, and their families.

Topic C5a) The information given to patients (or their parents) about the risk of non A, non B Hepatitis before their treatment with blood or blood products; b) the tracing and testing of patients who might have been exposed to the virus through their treatment with blood or blood products; and c) the information given to patients who might have been infected, or who were found to be infected, and their families.

### *Summary of the witness statements of the relatives*

- Twenty-nine witnesses were relatives of patients who had also provided the Inquiry with a witness statement. Of those witnesses, 13 relatives made statements about six patients between them, and the remaining relatives gave a statement about 16 individual patients;
- Seven witnesses were relatives of eight patients (one witness was related to two patients) who acquired HIV and/or Hepatitis C from their treatment for haemophilia. Of these eight patients, three were co-infected with HIV and Hepatitis C from their treatment; one patient had acquired HIV and his relative suspected that he had also acquired Hepatitis C; one patient had acquired HIV and his relative was unaware if he had been tested for Hepatitis C; and two patients had acquired Hepatitis C only. Four of the eight patients had died.
- Nine witnesses were relatives of eight patients (two of the relatives were related to the same patient) who had acquired HIV and/or Hepatitis C from blood transfusions. One patient had acquired both HIV and Hepatitis C from a blood transfusion, and the remaining seven patients had acquired Hepatitis C from a transfusion. Seven out of the eight patients had died.

### **The reaction of patients and relatives to diagnosis with HIV and/or Hepatitis C**

#### *Diagnosis with HIV*

**4.9** Invariably the patients who were diagnosed with HIV and their relatives felt fear, and some of them also felt anger. In the mid-1980s the publicity surrounding HIV was horrific and the prognosis for someone diagnosed with HIV was very poor.<sup>5</sup>

**4.10** One witness was told, within six months of her haemophiliac brother dying of AIDS contracted from infected blood products, that her seven-year-old son had acquired HIV from his haemophilia treatment. This witness' son subsequently died in 1994, aged 16, of AIDS.

**4.11** A mother of a 14-year-old boy described hearing the news that her son had been infected with HIV as being 'like a sledgehammer to the face'. Her son stated that, initially, when he was told his diagnosis, he did not take in the enormity of it. When he did understand his diagnosis he changed from doing fairly well at school to dropping out of school at the age of 16 with no qualifications. He started drinking alcohol and he stated that he was probably an alcoholic by the time he was 18 years old.

**4.12** Another patient described the time he was diagnosed with HIV as being 'an extremely stressful time' for both him and his wife due to the poor information available about the virus, and their concern for the future.

#### *Diagnosis with Hepatitis C*

**4.13** Most of the patients who were diagnosed with Hepatitis C, and their relatives, had not previously heard of the virus. They did not know the implications of it and, in the early years of the emergence of the virus, doctors were unable to provide them with much information about it.<sup>6</sup>

---

<sup>5</sup> See Chapter 5, *An Examination of the Effects of Infection with HIV on Patients and their Families, Including Treatment*, paragraph 5.17.

<sup>6</sup> See Chapter 34, *An Investigation into the Systems in Place for Informing the Patients About the Risks – Hepatitis C*, paragraphs 34.7–34.8.

**4.14** The patients and their relatives were shocked and upset when the patients were diagnosed with Hepatitis C. They described feelings of disbelief, uncertainty and fear. The lack of certainty about what the diagnosis might mean for the patients in terms of symptoms and prognosis exacerbated witnesses' fears. Many patients believed that diagnosis with the virus meant that they had a shortened life expectancy. When patients and their relatives discovered that the patient had been infected with the virus for a number of years, many believed that this meant that the patient's life expectancy was even shorter. At the same time, for many patients, their diagnosis with Hepatitis C provided them with an explanation for how they had been feeling, some for a long period of time.

**4.15** Some patients described experiencing feelings of shame and of feeling 'dirty' as a result of their diagnosis with Hepatitis C. The questions, which many patients were asked by medical professionals at the time they were diagnosed with the virus, may have contributed to such feelings. Many patients were asked if they had abused intravenous drugs, abused alcohol, been promiscuous or had tattoos. One patient, who suffered from obsessive compulsive disorder at the time of her diagnosis with Hepatitis C, stated that after her diagnosis she scrubbed herself until she bled.

**4.16** For those patients with haemophilia, who had already endured the outbreak of HIV, being diagnosed with Hepatitis C was a new blow. As one patient stated 'I was flabbergasted. I thought I was going to die. I asked myself when my bad news was ever going to end. We had just come through the highly publicised AIDS scare'.

**4.17** A patient described her shock when she was diagnosed with Hepatitis C after previously being diagnosed with HIV, both acquired from a blood transfusion. She stated that it was 'quite a lot to take in'. She felt shocked, hurt and angry. She became hysterical.

**4.18** Some patients were very worried that, having been unaware that they had Hepatitis C, they might have infected others, in particular their close relatives. One said:

Discovering I was Hepatitis C positive was a nightmare, a total nightmare. I was devastated at the thought of having potentially infected my wife and children. I was extremely relieved that my wife is negative for Hepatitis C.

**4.19** Two patients had given birth to children after acquiring the virus, but before their diagnosis with it. They were both extremely worried that they had passed the virus to their children. The children, who were subsequently tested for the virus, were found to be negative. Another mother worried that she had passed the virus to her daughter when her daughter had attended to a cut on her mother's foot. They both endured an anxious wait for the daughter's Hepatitis C test results, which were negative. A few patients had donated blood while they were unaware that they had Hepatitis C.

**4.20** In addition to the worry about having infected family members and others, many patients were concerned about the impact their diagnosis with Hepatitis C would have on their family. They were concerned that their symptoms would mean that they would be unable to care for their family or that they would die leaving their family members to cope without them.

**4.21** Some witnesses tried to ignore the diagnosis and others tried to find out more information about the virus themselves. This was difficult for those who were diagnosed with the virus, and for their families, before the advent of the internet. Even after the

availability of the internet, not all homes had access to it. Some of the information witnesses found frightened them. A patient who was infected with Hepatitis C stated that she was horrified by information she discovered on a website which told her how to arrange her own funeral and how her body would be treated after her death. She stated that this information 'profoundly affected her'.

### **Symptoms of HIV**

**4.22** The natural history of HIV and AIDS, including the signs and symptoms of infection, as now understood, is discussed in Chapter 8, *Knowledge of HIV/AIDS Now*. This provides a general background to the witnesses' evidence.

**4.23** One witness stated that when her son developed AIDS, 'everything focussed on getting [her son] to eat'. Her son did not eat enough and he suffered great weight loss. He developed eye disease and then tunnel vision. This witness stated, 'The worst thing about the whole business was that [my son] gradually went blind. None of the other kids [who attended the same Haemophilia Unit and had AIDS] had this and it made him depressed and vulnerable'. Her son subsequently died of AIDS aged 16.

**4.24** Another witness described the decline of his wife before she died from AIDS, aged 51 years. She became weaker over the years and suffered significant weight loss. 'Even the smell of food made her sick' and latterly she was tube fed. She weighed less than six stone when she died.

**4.25** A patient who was diagnosed with HIV as a teenager stated that he developed a bad chest infection when he was in his 20s. This required treatment in hospital. When he was in his late 20s he was diagnosed with non-Hodgkin's lymphoma, an AIDS-related cancer. He stated that he now has HIV-related mental health symptoms including dementia and post-traumatic stress disorder. He suffers from violent and aggressive thoughts, poor memory and cognitive processes, flashbacks and sleep disturbance.

**4.26** One patient, who was diagnosed with HIV when he was 30 years old and then later with Hepatitis C, has developed type 1 diabetes. He is now insulin dependent. He has been admitted to hospital with diverticulitis (a digestive condition affecting the large intestine), pneumonia and pleurisy. He now has cirrhosis. He has suffered from fluid retention, 'yellow tinges' in his eyes, varices, spider naevi (red veins resembling the shape of a spider beneath the surface of the skin) and encephalopathy (damage to the brain characterised by confusion, cognitive impairment and lethargy). These latter symptoms are attributable to Hepatitis C.

**4.27** A witness whose two sons acquired both HIV and Hepatitis C from their haemophilia treatment stated that they had both developed AIDS. One son developed sores on his back, bleeds in his stomach, liver and kidney problems, loss of weight and general weakness to the extent that he could barely walk. His other son also lost a lot of weight and developed arthritis, the latter perhaps due to the Hepatitis C virus (HCV) as opposed to HIV. Both sons suffer from severe depression.

**4.28** The wife of a man with both HIV and Hepatitis C stated that her husband's health has deteriorated 'dramatically' over the past 14 years to the extent that he now requires 24-hour care. He has little energy, tires easily and sleeps a lot of the time.

## Symptoms of Hepatitis C

**4.29** The symptoms of Hepatitis C described by the patients and relatives ranged from no symptoms at all to a number of severe symptoms. Most of the patients reported a gradual onset of symptoms and often, initially, patients thought the symptoms were caused by something else, for example having a young family or working hard. A number of patients stated that they 'did not feel right', highlighting the unspecific nature of the symptoms of Hepatitis C.

**4.30** Specific physical symptoms reported by patients and attributed by them to their infection with HCV were:

- Lethargy, tiredness, exhaustion, reduced physical ability, heart palpitations after physical activity.
- Night sweats, insomnia, erratic sleep – one witness stated that he would never wake up feeling as if he had experienced a good night's sleep.
- Little or no appetite, indigestion, nausea, vomiting, weight loss.
- Anaemia.
- Jaundice.
- Discomfort and/or pain in the abdominal area.
- Irritated and/or itchy skin, skin discolouration, red hands, rosacea, boils, spots, bruising easily.
- Muscle pain, joint pain, stiffness, cramp, rheumatoid arthritis.
- Neuralgia and neuropathy (damage to the nerves and nervous system).
- Headaches.
- Having a compromised immune system and being prone to infection.
- Hot flushes, feeling the cold, uncontrollable shaking.
- Low mood and mood swings, depression, poor concentration, poor memory, poor motivation, irritability, confusion, anxiety and panic attacks, suicidal thoughts, incidents of self-harm.

**4.31** The more serious symptoms described by a smaller number of patients and attributable to severe liver disease were ascites (accumulation of fluid in the abdomen), varices (varicose veins), inflammation of the liver and of the spleen, hepatocellular carcinoma and encephalopathy (damage to the brain characterised by confusion, cognitive impairment and lethargy).

## Treatment for HIV

**4.32** The treatment for HIV, including the development of it over the years, is described in Chapter 9, *Knowledge of HIV/AIDS Now*.

**4.33** The first treatment which doctors prescribed for HIV was Zidovudine (also known as AZT). A witness, whose son was treated with Zidovudine in the mid-1980s when he was eight years old, believes that the start of her son's treatment with Zidovudine coincided with the start of his declining health. She now wonders if he was prescribed too large a

dose of the drug. Her son was also treated for eye disease with an intravenous drug which took two hours to administer. He was prescribed antiemetic medication to control nausea. Her son subsequently died. Another witness described how her husband was wary of Zidovudine, having seen a number of his friends and relatives take it and subsequently die. Her husband refused treatment with Zidovudine.<sup>7</sup> He later suffered a psychotic reaction to his treatment with Efavirenz.<sup>8</sup>

**4.34** One patient described having to take his antiretroviral medication every four hours. He used to have to wake himself up at four o'clock every morning to take the dose due then. He found this treatment disruptive and upsetting. The same patient stated that there were a lot of 'harsh' side-effects from antiretroviral medication and that this was especially true of the first-generation products. He said, 'I knew I had to take them if I was to live'. The side-effects from which he suffered as a result of his treatment for HIV over the years have included a burning feeling in his stomach, nausea, vomiting, malaise, generally feeling unwell, anxiety, depression, insomnia, peripheral neuropathy (damage to the nerves and nervous system), joint and muscle pain, sexual dysfunction, diarrhoea, flatulence, headaches, depression, anxiety, loss of concentration, poor sleeping and difficulties eating. This same patient was also treated with chemotherapy and radiotherapy for his AIDS-related non-Hodgkin's lymphoma.

**4.35** Another patient stated that his treatment with antiretroviral medication has caused a thinning of his bones. As a result of this he sustained a spiral fracture of his femur after falling down stairs. Whilst being treated for this in hospital he acquired an infection with E-coli.

**4.36** Another witness' wife was treated with Zidovudine, Didanosine and Immunoglobulin before she died of AIDS. This witness stated that he had 'every praise' for the staff who treated his wife and the care which she received.

### **Treatment for Hepatitis C**

**4.37** Further detail about treatment for Hepatitis C is narrated in Chapter 13, *Knowledge of Viral Hepatitis Now*. In summary, it may include monitoring of a patient's condition by examination, blood tests, ultrasound, CT scan, MRI scan, Fibroscan and liver biopsy and treatment with medication and, if necessary, a liver transplant. The medication to treat Hepatitis C was initially Interferon, then Interferon and Ribavirin and is now Pegylated Interferon with Ribavirin.

**4.38** One aspect of treatment for Hepatitis C, which a number of patients commented upon, was the fact that they had to attend the infectious diseases unit of the hospital for their treatment at the same time as those who had become infected as a result of drug misuse. 'Most people attending the clinic had a drug problem. All conversations in the waiting area were about getting access to drugs. This was a complete culture shock to me.'

**4.39** Two patients described attending clinic appointments at the same time as heavily guarded and handcuffed prisoners. One patient stated that if the prisoners 'kicked off' they would be seen before her. She found the experience 'uncomfortable'. The other patient found it upsetting attending her appointment at the same time as prisoners. She

---

<sup>7</sup> See Chapter 8, *Knowledge of HIV/AIDS Now*, paragraph 8.36.

<sup>8</sup> Efavirenz is a non-nucleoside reverse transcriptase inhibitor used to treat HIV since about 1998.

was also very concerned that someone she knew would see her attending the infectious diseases unit. In fact, one of her work colleagues saw her there and asked her about her illness. She stated that rumours about her then circulated at work.

**4.40** A patient who was diagnosed with Hepatitis C in 2009 has described his treatment as chaotic. When his wife phoned the hospital, in 2010, for test results she was told by the doctor's secretary that she had to understand that 'hepatitis was a chaotic illness which meant that it was a chaotic clinic for people with chaotic lifestyles'. The patient's wife said, 'I appreciate it is a chaotic clinic for people with chaotic lifestyles but we are not like that'. A number of patients spoke about their clinic appointments being cancelled.

### ***Medication for Hepatitis C***

**4.41** It was apparent from the witness statements that a number of factors affected a patient's decision to start treatment with medication for Hepatitis C, and often made the decision about whether and when to start treatment difficult. These factors included the uncertainty about the best time to undergo treatment, the potentially severe side-effects which the medication can cause and the poor prospects of success of the treatment. It was particularly difficult for patients who had no symptoms of the virus, to embark on a course of treatment which might cause them very significant side-effects and which might fail.

**4.42** A number of patients chose not to undergo treatment with medication for Hepatitis C. Their reasons for this decision included: believing that the treatment would not help them and might, in fact, make their condition worse; being too scared to start the course of treatment; and a concern that the medication would worsen a witness's pre-existing mental health or physical symptoms. Some patients were required to undergo a psychiatric assessment before being allowed to start treatment.

**4.43** Other patients chose to delay their treatment mainly for family reasons, for example having young children or wishing to start a family. Some of these patients then faced a delay when they decided they were ready to start the treatment. This was a difficult period for them and caused them anxiety.

**4.44** For some patients starting treatment for Hepatitis C brought home their diagnosis with the virus. One patient stated:

The worst thing about starting the Interferon was it forced me to acknowledge that I had this life threatening virus in my blood. At that point my future was impossible to contemplate and I found myself thinking what music I would like at my funeral. That's how it made me feel. I always felt I was a strong individual and that I could handle anything von Willebrand's disorder threw at me. This was something else, far beyond my control and it loomed over me blocking out the light.

### ***Side-effects of Interferon and Interferon combined with Ribavirin***

**4.45** Most patients were warned about the side-effects they might experience from their treatment with Interferon and Interferon and Ribavirin but many stated that the treatment was much worse than they had expected. While a few patients experienced some or no side-effects, the majority experienced a number of different side-effects. The impact of these ranged from having little effect on a patient's life to rendering a patient bed-bound and incapable of taking part in work, family or home life. These impacts are described in more detail in paragraphs 4.47–4.49 below.

**4.46** Treatment with Interferon was administered by way of injection usually given three times a week. In more recent years, treatment with Pegylated Interferon may be injected weekly. Patients were taught to inject themselves. Some had difficulty with this and either their family members helped them, or they attended their GP's surgery and the treatment was administered there. Some patients took their weekly treatment on a Friday evening in the hope that they would recover from the worst effects of it over the weekend, and be fit for work on the following Monday. Many patients were advised to take paracetamol at the same time as their dose of Interferon and some patients found that this helped the side-effects.

**4.47** Side-effects reported by witnesses and attributed by them to treatment with Interferon were:

- Flu-like symptoms – raised temperature, headaches, sweating, feeling hot and cold, tiredness, lack of energy, loss of appetite, weight loss.
- Insomnia, disturbed sleep and exhaustion.
- Nausea, vomiting, stomach cramps, diarrhoea, dehydration (requiring in-patient treatment).
- Insatiable thirst, change in sense of taste.
- Depression (requiring treatment with antidepressants), irritability and anger, mood swings, anxiety attacks, confusion, cognitive impairment.
- Worsening of joint pain.
- Vertigo.
- Developing an underactive thyroid (which requires permanent thyroid replacement treatment).
- Loss of hair.
- Itchy skin, hardening of the skin and a smell coming through the skin.
- Uncontrollable shaking.
- Seizures.

**4.48** Additional side-effects reported by witnesses and attributed by them to treatment with Interferon or Pegylated Interferon together with Ribavirin were:

- Dry skin.
- Dry mouth.
- Straightening of the hair.
- Anaemia.
- Hypertension.
- Dizziness and light headedness.
- 'Riba-rage',<sup>9</sup> panic attacks, disorientation.
- Constipation.
- Peripheral neuropathy.

---

<sup>9</sup> 'Riba-rage' is a term used for the intense depression and irritability that some patients taking treatment for Hepatitis C have experienced.

- Neutropenia (an abnormally low level of neutrophils, a type of white blood cell).
- Infections, for example dental abscesses.
- Mouth ulcers, thrush.
- Vivid nightmares.
- Palpitations and shortness of breath.<sup>10</sup>

**4.49** Examples of other, less common, side-effects experienced by patients were:

- One patient suffered blood loss during treatment with Interferon and Ribavirin and required a transfusion.
- Another patient developed septicaemia while being treated with Interferon and Ribavirin. He then developed swelling of his prostate gland which he was told was caused by the septicaemia. His treatment with Interferon and Ribavirin was stopped immediately.
- Another patient stated that his ALT level increased to four times the level it was prior to treatment.

**4.50** Some patients worried about the impact their treatment would have on pre-existing medical conditions. One patient stated that he was unable to take anti-inflammatory medication for arthritis during his treatment as he was unable to eat. Women taking the treatment were strongly advised not to become pregnant during the course of the treatment due to the risk of it causing birth defects or the death of the unborn baby. For the wife of one patient, this meant that there is now a greater age gap between her children than she would have liked.

**4.51** The treatment caused a wide range of mental health symptoms for a number of patients and often these were severe. Some patients were prescribed anti-depressant medication during their treatment for Hepatitis C. One patient became severely depressed and started taking an overdose of paracetamol before he was interrupted by a telephone call from his mother. He stated, 'That time felt like a dark hole with no way out'. Another patient described waking up one morning during his treatment and not knowing who he or his wife was. One patient was not allowed to be left alone with her young nephew in case she 'flipped'. Another patient stated:

As well as not feeling well, I felt at risk of blowing up with anger and frustration at small provocation. I tried to avoid getting into any such situation as far as I could. For example, at that time two of our children were at university and the two teenagers were at home, and I avoided anything which might lead to a dispute because I did not trust myself to be reasonable. My wife had to deal with things like that as well as with me.

**4.52** Some patients suffered a loss of confidence as a result of the treatment:

I was rarely able to go out. I had to pick my moments to go into shops. Sometimes I drove to the shops but had no confidence to get out of the car and so I just drove home again. A few times I drove when I really was not capable of driving safely as I had tunnel vision and could not see the road properly.

---

<sup>10</sup> See Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraphs 13.106 and 13.107 for side-effects of these treatments, including the list set out in the SIGN guidelines of the side-effects of Pegylated Interferon and Ribavirin.

**4.53** For many patients their treatment with Interferon or Interferon and Ribavirin was the worst aspect of their infection with Hepatitis C. A number of patients and relatives described the treatment as horrendous:

The side effects of the treatment were horrific. It was the worst treatment I have had in my life and I would never do it again. It was like having the worst flu you can imagine. My immune system became so low I was totally open to infection. I got lots of infections. If I cut myself it took a long time for cuts to heal. I lost the sensation in my feet. My hair fell out, I lost a lot of weight and I looked like a corpse. I regularly collapsed into long stupors of sleep. On a few occasions when my husband came home and found me like this he thought that I had died. I suffered from spinal pain and from pain at the injection site. In the end I chose to stop the treatment due to the side effects.

I took the [Interferon and Ribavirin] treatment for 48 weeks. It was horrific and never again. I have had chemotherapy, a mastoid operation and deaths in the family and other personal stuff but I have never, ever experienced anything like the Interferon and Ribavirin treatment.

After approximately six weeks I began to notice changes in my sleeping and eating habits. I can sleep very easily now when I go to bed at 9.30pm – 10pm, whereas before I was a bit of a night owl, staying up until the early hours watching television, reading etc. Several days a week I feel tired, lethargic, listless, nauseous, uninterested and have no attention span in what is happening around me. Conversations, television and reading all leave me thinking afterwards, 'What actually happened there'. For a short-time I actually felt like hell. I was constantly nauseous, tired, 'wabbit', had indigestion, heartburn and I just lay in my bed suffering and feeling sorry for myself with absolutely no appetite.

**4.54** Some patients thought that they or their relatives were going to die during the treatment. One witness stated:

The treatment [Interferon and Ribavirin] my brother had was horrendous .... I do not know how he survived it. I think he should have been hospitalised but he was determined not to go in to hospital. He was very weak and suffered a lot of pain. He was unable to sleep and suffered from "shocks". He lost a lot of weight and was unable to eat. My brother always had someone in the house when he was having a bath as he was so weak. My son, my other brother or another member of the family was always there in case anything happened. I worried throughout the treatment that he was not going to survive it. I have seen my father and a friend die of cancer but watching my brother undergo this treatment for a year was worse than that. It was the worst thing I have ever seen. Unless you see someone go through this treatment you cannot understand how horrendous it is.

**4.55** The severity of the side-effects which some patients experienced, and which their relatives observed, caused some to have their dosage of the treatment reduced and others to have the treatment stopped altogether. This caused great disappointment to the patients being treated and their families as the patients faced an uncertain future. Many patients showed great strength and fortitude in managing to continue with their treatment despite experiencing severe side-effects. It was apparent that the hope of ridding themselves of the virus gave patients the motivation and determination to do this.

**4.56** For a number of patients and their relatives the treatment was successful. For the patients, this made what they had suffered by way of side-effects worth it. However, as well as their feelings of joy and relief, some patients described feelings of uncertainty and doubt as to whether they had cleared the virus for good or whether it might return. The uncertainty of doctors about this, particularly in the earlier years, is likely to have contributed to these feelings.

**4.57** The treatment of a similar number of patients was unsuccessful, in some cases after three or four different courses of treatment. Witnesses expressed their devastation and disappointment about this. The feelings of many patients were exacerbated by the severity of the side-effects they had endured. One mother described her shock at her son's second treatment failing as she 'felt sure there was no way a second treatment would fail. My son suffered two massive blows to his life and future health'. A number of patients stated that they would refuse to take the treatment again due to its side-effects.

**4.58** For some witnesses the disappointment of the treatment failing was compounded by the 'false hope' given by blood tests at the end of treatment indicating that a patient had cleared the virus, only for the blood test six months later to show that the virus had returned. One witness described how she felt after her husband's blood tests looked promising:

For the first time ever, I allowed myself to think about life without Hepatitis C and realised all the ways in which it overshadowed our lives like a persistent cloud; uncertainty, anger, long term financial implications, having to decide about and attempt future treatment; what that meant for job prospects and financial security; the ongoing risk of cross infection; the worry of my husband's health declining and what that would mean for my health, my children, my work, our income, our quality of life. When the virus reappeared in his blood soon after the treatment ended I found this extremely hard to cope with because having seen how improved our life would be if we were free of the virus, these hopes were then dashed.

**4.59** Some patients described the side-effects of the treatment persisting for some months, even years, after the treatment ended.

I have never recovered from the Interferon treatment. Physically, I looked as though I had aged ten years. My hair turned from black to grey. My back and posture became stooped. My sons thought I looked old. My sister-in-law was flabbergasted when she saw me. She barely recognised me. I never looked nor felt like a young man again. After the treatment ended I never bounced back. I still have to take antidepressants. My depression is not as severe but I still need to take the medication. My wife and I have no sexual relations. For two years this has been getting worse. In my opinion this loss of libido is directly linked to the side effects of Interferon treatment. I try to get out of the house to meet my male friends who all thought I was going to die during the treatment. They are also of the opinion that I aged tremendously after this treatment.

**4.60** One patient who suffered from side-effects of Interferon but whose treatment ultimately was successful, described the effect of the treatment as follows:

Luckily by December 1999 I knew that the treatment was working. I suddenly felt better and between December 1999 and July 2000 I started putting on weight and feeling better in myself. I had more energy, my colour improved

and I felt excellent. It was as though I had been blind and had just put my first glasses on. I soon realised how long I had been ill for. As I have already said I had got used to feeling ill and had forgotten what being healthy was all about.

### ***Other treatment***

**4.61** A few patients have undergone banding of oesophageal varices (varicose veins on the oesophagus). One patient stated that a varix burst as he underwent the procedure and he lost four pints of blood.

**4.62** One patient who received a liver transplant described how he felt afterwards:

Despite all the adversity I now feel like a 20 year old. I have never felt so well in my whole life. I am building up my fitness. I want to do so many things with my life which were previously denied to me due to illness. Hepatitis C ended my working career and career opportunities. With Haemophilia I always managed to work albeit with occasional absences. Hepatitis C caused my irreparable liver disease and I nearly died due to this. My end stage liver disease made me housebound and highly dependent on others to survive. I had no quality of life for years. Hepatitis C caused a sharp decline in my health from 1997 to 2009. I am keen to rebuild my life by going to night school. I am keen to learn how to play a musical instrument. I want to travel. I got my driving licence back in ... 2009. I now drive to my own appointments at the [hospital]. I have freedom to do these things because I am cured from Hepatitis C induced liver disease. I have energy again. I feel optimistic.

### ***Alternative therapies***

**4.63** Some patients have tried alternative therapies to alleviate their symptoms of Hepatitis C and believe that these have caused some improvement of their condition. Such therapies include milk thistle, meditation, aromatherapy, vitamin supplements, omega 3 supplements, herbs, acupuncture, tai chi, receiving treatment from a chiropractor, crystals and a healthy diet.

## **Other impacts of infection with HIV and/or Hepatitis C on patients and their relatives**

### ***Personality and lifestyle***

**4.64** A number of patients described their diagnosis with HIV and/or Hepatitis C and their fear for the future as weighing on their minds. One patient described his diagnosis with Hepatitis C as 'a weight around my neck. It's always there'. Patients have coped with this in different ways but it is apparent that the feelings they have experienced have been exacerbated by the stigma and isolation surrounding both viruses.<sup>11</sup>

**4.65** The following are excerpts from a number of the witness statements describing how infection with HIV and/or Hepatitis C had affected patients:

I don't have a life anymore. I exist. The Hepatitis C virus has taken everything. I don't know who [the witness's name] is anymore. I used to be so outgoing. I travelled a lot and was very sporty. I used to enjoy rock climbing, swimming and gardening. I rode a motorbike. I enjoyed socialising. Now I have just one

---

<sup>11</sup> These are discussed in more detail in paragraphs 4.95–4.113 below.

friend. The Hepatitis C virus has 100 per cent changed me. I feel a drain on everyone as I rely on everyone so much. I very rarely leave the house, only really to go to hospital appointments and this has been the case for about the last 10 years.

The impact of my infection with Hepatitis C has been huge. I suppose after all I have been through growing up with haemophilia it was the straw which broke the camel's back.

This diagnosis has changed me completely. I used to be a happy-go-lucky type of person. Now I stay at home and keep myself to myself. I go out once a week on a Wednesday when I go to the bank and pay bills. I keep thinking I am going to die. I cannot get it out of my head. It feels like a life sentence.

**4.66** A father stated that one of his sons 'went wild' when he was diagnosed with HIV as a teenager. His son thought that he was dying anyway and so what did his behaviour matter? His other son was also diagnosed with HIV. The family was devastated. Subsequently his sons watched a number of their friends, who attended the same haemophilia clinic as them, die of AIDS. Both his sons suffer from depression and he has had a nervous breakdown.

**4.67** The mother of a boy who died from AIDS when he was a teenager stated that her son withdrew from his friends as he became more ill as he thought that 'he was not much company'. She stated that, having been brought up with a brother with haemophilia and then subsequently having a son with haemophilia, she feels as if she has had 'a roller coaster life. I have lived with haemophilia all my life and you always put the sick person first'.

**4.68** A mother stated that her son had lost all his confidence since finding out he was infected with Hepatitis C and he did not have a good self-image. Another witness who was diagnosed with Hepatitis C when he was a teenager stated that, had he not been diagnosed with the virus, he would have gone out drinking and socialising more. He stated that his lifestyle would have been different. He was 'very careful' as a single man and did not have any short-term relationships.

**4.69** One patient described the change in his lifestyle as a result of his symptoms of Hepatitis C. Before his diagnosis with Hepatitis C he had a wife, a successful career, a house and a boat. Since suffering symptoms of Hepatitis C and the side-effects of treatment he has lost all of these. He is now separated from his wife, homeless and living on benefits. His sister stated that it was embarrassing for him to meet up with his old friends as people remembered him as 'so very generous'. Now he can no longer afford to be generous. She stated that her brother is lonely with no one to share his life with.

**4.70** Many witnesses spoke about themselves or their family members being unable to go on holiday or to take part in hobbies or activities which they previously enjoyed, due to being unwell as a result of the symptoms of the virus or their treatment for it. Others spoke of withdrawing from activities due to the fear of infecting others with the virus. A couple of patients with Hepatitis C spoke to feeling left out and conspicuous as a result of being unable to drink alcohol socially.

**4.71** Relatives spoke about their worry and concern for their family members who were infected and their fear for the future. The wife of a man diagnosed with HIV stated:

The consequences of what happened to us after [my husband] was told of his HIV positive status are vast and a lot of it is too difficult to tell in this statement. Before being told that [my husband] was infected we were a happy family with everything to look forward to. Life changed to fear, uncertainty, worry and most of all secrecy.

**4.72** Relatives also spoke to the changes in patients following their diagnosis with the virus:

It feels like our whole life has been turned upside down. It has left me married to a stranger. The happy-go-lucky person I married is no longer here. Our family life is a lot different now. If we went somewhere and were doing something, my husband used to be loud and lively. Now he can't be bothered. He used to see his brother every Friday night, now he can't be bothered. Even going grocery shopping is an escapade, half way round the shop he feels tired. He is now a crabbit, old besom. Some days he feels very depressed and some days he is too tired to do anything. He sometimes needs help out of the bath and to get downstairs. He is sometimes scared to be alone and wants company, then he doesn't like when he has company. My husband is not interested in anything. His whole life now revolves around sleep and being exhausted. He's like a stranger to folk now.

### ***Relationships and family life***

**4.73** Many patients described the strain which their own or their relative's infection with Hepatitis C and/or HIV placed on their marriage or relationship. A number of witnesses attributed the breakdown of their marriage or relationships to their own or their spouse's/partner's infection with HIV and/or Hepatitis C. Some patients thought that the implications of their own infection had been too much for their partner to cope with.

**4.74** One woman stated that, during their son's illness with AIDS, 'Needless to say our marriage was not important. Both of us focused on trying to keep [our son] alive'. Following the death of their son, she and her husband underwent some courses of IVF and worked at their marriage. Despite having 'a few good years' they are now in the process of divorcing.

**4.75** Another witness stated that her husband suddenly started to wash his own crockery and cutlery. He used the same two cups and would not let anyone else use them. He started to wash his own underwear. Then he told his wife to leave and she did so. They separated at that time. Later she discovered (after finding correspondence from the Skipton Fund) that her husband had acquired Hepatitis C. Her husband has since died.

**4.76** At the time one patient was diagnosed with Hepatitis C his partner was pregnant. Their baby was born with a cyst on the brain and subsequently died. His relationship with his partner broke up soon after as they were both devastated at the loss of their child and his partner believed, at that time, that the baby's health condition was 'in some way' caused by his Hepatitis C.

**4.77** Many witnesses stated that the nature of their relationship with their spouse or partner changed as their spouse or partner became his or her carer or they cared for their relative. Some carers found themselves torn between looking after their spouse or partner on the one hand and the rest of the family on the other. One woman described the impact of her husband's treatment for Hepatitis C:

The treatment and its side-effects have had an impact upon my role as mother and wife. I tried very hard to ensure that my husband's needs and daughters' needs are met. The children sometimes got the brunt of my husband's irritability and mood swings. I had to keep reassuring them and explaining that it was down to the medication. It is most unlike my husband because he is usually such a placid character. It is a fine balance and has been a difficult time. I wanted to keep everything as normal as possible. It was very challenging as I also continued to work full time and was actually awarded with a certificate for 100% attendance for the year. I don't know how I did it. I never said to anyone about the situation. I really struggled to keep upbeat. I confided in my GP about the pressure at home.

**4.78** One patient and her relatives described how her treatment for Hepatitis C affected her relationship with her husband in the last few months of his life. Her husband was undergoing chemotherapy treatment while she underwent treatment with Interferon. The side-effects of the Interferon treatment caused her to be short tempered with her husband. She became critical of him and spoke to him with venom. Her son stated that this was not natural and his mother had not spoken to his father like that during 40 years of marriage.

**4.79** A patient, who subsequently died after he and his wife had given their statements, described Hepatitis C as having 'destroyed' his relationship with his wife and their sex life. This patient's wife stated:

We don't go out and are unable to make plans. Our relationship has suffered severely. I feel I have gone from being his wife and friend to being his carer. We no longer have a sexual relationship or do anything together as a couple. I find he has become dependent on me for a lot of things, his concentration is not so good and he has lost some of his confidence. I also find it very hard to talk to him and to get him to talk to me. We are like brother and sister instead of husband and wife and I do not see this improving. I feel sad that this has happened through something which was not the fault of [her husband].

**4.80** A number of individuals spoke about the impact of HIV and Hepatitis C on their sexual relations. Some stopped having sexual relations with their spouses or partners after their diagnosis with HIV and/or Hepatitis C, for fear of infecting them. One stated that, other than when she and her husband conceived their children, they have had to use barrier methods of contraception at all times as opposed to other methods, like a vasectomy, which are open to their contemporaries. She said, 'We never expect to be free of the fear of transmission'. One patient, having read that the virus could be transmitted sexually, contacted all his previous girlfriends and explained the risks to them.

**4.81** One patient stated that he was in denial after being diagnosed with HIV, and he continued to have unprotected sex with his wife. She became pregnant and was advised that the baby could have HIV and would not have a good chance of survival. She underwent

a termination of the pregnancy. During this procedure his wife was treated as infectious and kept in a side room in the hospital. This experience was 'devastating' for his wife.

**4.82** A number of patients who are not in a relationship spoke of the difficulty in forming relationships when infected with Hepatitis C and/or HIV. A number posed the question, 'How do you tell someone (with whom you would like a relationship) that you are infected with Hepatitis C or HIV?'

**4.83** A husband who acquired Hepatitis C from his wife stated that his marriage came under 'an immense strain' when his wife was advised that they had different sub-types of the virus. They had been together since they were young and he felt that she would be wondering where he had got the virus from if he had not acquired it from her. His wife was later informed that she had two sub-types of the virus and that she had only infected him with one.

**4.84** Family members have described watching their relatives suffer from the symptoms of both viruses and from the side-effects of treatment. Some have watched their relatives die, which understandably has had a profound and lasting effect on them.

**4.85** Some witnesses spoke of their relative turning to alcohol as a way of dealing with the illness and its impacts. One witness stated that his father's death from Hepatitis C had 'a massive impact' on the whole family. The witness stated that he is now a binge drinker and, since his father's death, he has 'come off the rails' a few times.

**4.86** Another witness described the effect on him of his father's illness with HIV and subsequent death. He was eight years old when his father died. He remembered that his father was unable to do much actively with him although he used to take him fishing and told him a story every night. He remembers his father being in hospital most of the last year of his life and visiting him there. He remembers the night his mother told him that his father was dying. He stated 'It was devastating. I didn't see my father again'. His father's death completely changed his relationship with his paternal grandfather who unfortunately became very depressed and died a few years later. His maternal grandfather helped his mother raise him. After his father's death he felt that he was missing out not having a father to put him to bed or to tell him a story. He believes that his mother was looked down on by some people because she was a single parent. He stated that his father was a gifted musician but he never had the chance to learn from him. He would have loved his own children to have known their grandfather.

**4.87** Many patients expressed their concern, distress and fears about the effect that their illness has had and may have on their family in the future. Their fears include being unable to look after their family, needing to be looked after by them or dying and leaving the other members of their family to cope. Likewise, the relatives expressed their worries about their family members who are infected with HIV and/or Hepatitis C becoming ill or dying. One mother stated:

I used to worry that my son would not meet anyone to share his life with due to his Hepatitis C. I am so overjoyed that his new wife has accepted him and loves him as he is. They met at University and were close friends first. She is perfect for him. However despite my happiness I cannot stop being worried about the future. I worry about the risk of sexual transmission, the problems they may encounter should they decide to start a family and the worst case scenario of his new wife bringing up a family on her own should he predecease her due

to Hepatitis C. They do not have any children and I know that this is probably yet another huge blow to both of them whilst they weigh the risks up, given the risk of sexual transmission of the Hepatitis C virus. This is not something he talks about with his mother, but no doubt he has worried about this also. There remains a lot of uncertainty about his future prognosis.

**4.88** Witnesses described the strain on family relationships caused by their own or their relative's illness as a result of HIV and/or Hepatitis C.

When our children were very young they suffered by being separated from me on the numerous occasions I was in hospital. While young they were unaware of the serious health problems I was dealing with, but in their teenage years their lives were shaped by the anxiety of seeing their mother in extreme pain and suffering and they had to endure the worry of test results and hospital admissions. In their final years at school they both experienced emergency ambulances coming to the house on a number of occasions. They cared for me in every way they could but my husband and I did not want them to witness any more of the daily suffering I had to endure or feel responsible for my care .... Today when they visit, they voice their concerns about the large amount of medication I take each day and worry that I may die soon.

**4.89** Witnesses described seeing other family members, sometimes their parents, upset as they tried to cope with the full effects of the illness. They also spoke of the patient being unable to contribute to or to take part in family life as she or he did before:

I have seen my Dad's health deteriorate over the years and he has become increasingly dependent on the family to help him do everyday things and assist him attending appointments and GP surgeries. He cannot participate in a lot of family functions and activities and has been unable to go on holiday for a number of years. These are the things I miss most – being a family and being able to do things as a family. He is not the same person now and I am sure this affects him in many ways. I think it affects relationships and he is concerned about the future, both his and the family.... I know that my Dad becomes frustrated that he cannot do more with [her disabled brother] due to his condition and help my Mum .... I feel that this condition has seriously and adversely affected my life and that of my family. I do not feel that I had a normal childhood due to this....

**4.90** One relative described seeing his father lose all confidence in himself during and after his treatment with Interferon. His father suffered depression as a result of this treatment. While this relative was a student, he used to go to work meetings on his father's behalf while his father sat in the car outside. Eventually he stopped going to university for a while as he was so worried about his father. He stated that, at times, he had to be with his father as he was worried he would take his own life. There were periods when his relationship with his father was difficult and now he believes that this was probably due to his father's symptoms of the virus. He stated:

I do not feel good about this now .... It has been totally distressing for me to see Dad like this. I feel so helpless and I find it stressful. I worry about him. It is very difficult to see someone, who you have looked up to and seen as a good role model, go through what he has been through and understand why this has happened.

**4.91** A difficult matter for a number of patients was telling their children about their infection. Patients described their children reacting in a range of different ways on being told this – being supportive of the other parent; being scared; worrying in particular that their parent was going to die; becoming very emotional and developing mental illness such as depression and anorexia nervosa. One parent described one of her daughters changing from being an outgoing, successful athlete to becoming a recluse after being told of her mother's infection with Hepatitis C. She also developed myalgic encephalomyelitis (chronic fatigue syndrome, also known as ME) and depression. This parent stated, 'I should be able to look after her but cannot [due to her own symptoms of Hepatitis C]. We have to help one another to get through the day'.

**4.92** A number of patients with Hepatitis C are concerned about their ability to have a family, with some believing that this is an option denied to them as a result of their infection. One witness described her and her husband's inability to have children as one of the most distressing impacts of his diagnosis with Hepatitis C. She and her husband both have fertility problems. Her husband has another medical condition. Having unsuccessfully tried fertility treatment they decided to explore the possibility of adoption. Two independent adoption agencies turned them down on the basis that her husband's medical condition together with his infection with Hepatitis C, meant that adoption would not be in the best interests of the child. She found this very hard to take and became very depressed.

**4.93** A number of patients infected with HIV and/or Hepatitis C feared that they might pass the virus on to relatives or other persons.

On a day-to-day basis I have to be really careful with my two young sons regarding my toothbrush. When I'm doing anything in the house where I could cut myself I always wear gloves and take extra precautions. Any time I do injure myself I find it very difficult not to panic when my children are in the vicinity. I am very paranoid about passing this disorder on to my children. It is clear to me that there will be many limits to the activities that I can pursue with my children, for example, I have already avoided all contact sports due to the risk of passing on the virus. Many of the feelings I had when I first learned I had Hepatitis C resurface and this can be upsetting.

**4.94** One patient stated that she is terrified to give her grandchildren a hug or a kiss in case they catch the Hepatitis C virus from her. Others described keeping their home very clean, using their own glasses and crockery and being very careful around their relatives.

#### *Stigma, secrecy and isolation*

**4.95** Many witnesses described having to deal with the stigma associated with the viruses as being the worst aspect of the infection. A large number of patients have not told their family members (including close family), friends and colleagues about their infection. The result of this has been that they live their lives with secrecy, sometimes with lies and they have become isolated from family and friends.

#### **HIV**

**4.96** Due to the adverse publicity about HIV in the 1980s patients and their families were encouraged by medical professionals to keep their diagnosis with HIV a secret.

**4.97** A mother (whose brother also had HIV) described how she and her husband were 'obsessed' with keeping their son's diagnosis with HIV a secret. One newspaper published

an article about HIV with the headline 'Killer Blood' which referred to her brother. This witness and her husband were concerned that their son would be excluded from school if the school became aware that he had HIV, and they did not want the press to start investigating their son. After their son's death, they told people that he had died of leukaemia.

**4.98** Another witness whose wife died of AIDS stated that, at her funeral, her coffin was covered with a tarpaulin and the flowers were put on the floor. Following her death his sons changed their names so that their children would not be bullied because of the stigma associated with HIV and Hepatitis C. At the time of his wife's death, he worked part-time as a mechanic. After her death he was told not to return to work because his wife had died of AIDS. He felt that neighbours were talking about him after her death. In her diary this witness's wife wrote about her inability to put her diagnosis with HIV out of her mind due to the constant publicity about it. She stated that the news stories about HIV and 'the way they jumped out of newspapers' did not let patients like her forget that they had the virus.

**4.99** One witness stated that, as a result of their secrecy after her husband's diagnosis with HIV, the closeness they previously had with their families has now gone and 'is something that can never be fixed'. She stated that they could not face her family 'because of all the lies' as they had not told anyone about her husband's diagnosis with HIV. They still keep away from their families.

### Hepatitis C

**4.100** Even today there is ignorance and lack of understanding about the Hepatitis C virus. Some people associate it exclusively with the misuse of intravenous drugs, abuse of alcohol, tattoos and even promiscuity. As a result of the stigma associated with it, a number of patients described feeling ashamed, embarrassed, self-conscious, contaminated and stigmatised by their diagnosis with the virus.

**4.101** Many worried how their family, friends and work colleagues would react to their diagnosis and chose not to tell them. This secrecy put a great strain on witnesses and their relatives who knew of their diagnosis.

**4.102** A patient who was diagnosed with Hepatitis C when he was 15 years old stated:

My parents worried about the potential prejudice I may suffer from others and so we decided together to only inform the immediate family about Hepatitis C. We did not tell friends and the teachers at school. The pressure upon us to keep the diagnosis secret was, and is still, immense. It is very hard to withhold information about yourself which is so personally consuming. The pressure to conceal this diagnosis continues to be a source of pressure to this day for me, my wife and my family. Some of my closest friends know about my haemophilia but I have never discussed Hepatitis C at any time. A constant source of worry for me is if my employers should find out or have to be informed. Will they understand what Hepatitis C and Haemophilia are? Will they be prejudiced against me? Will they consider it is some way deceitful of me that I have never told them despite no compulsory medical disclosures ever having been required?

**4.103** Some witnesses have experienced adverse reactions of family and friends to their diagnosis with Hepatitis C. One witness stated that her husband, who died as a result of his infection with Hepatitis C, was embarrassed by his diagnosis with the virus and did not wish anyone to know about it. His children found out about it when he started treatment with Interferon. One of his children stopped bringing his own children to their house and would not allow the witness to hold her grandchildren even although she did not have Hepatitis C. She stated that she should have had a close and meaningful relationship with her family but she has now lost contact with them as a result of her husband's infection with Hepatitis C.

**4.104** A patient, who lived in a small village, told a friend of hers that she had Hepatitis C. Their children were friendly but suddenly her friend stopped inviting her children to play and there was talk of her children having a virus. This patient and her family moved to a different village for a fresh start.

**4.105** Another patient stated that a relative of his told someone in their local pub that he had Hepatitis C. Rumours then spread that he had HIV. One patient stated:

I want to get people to wake up to the fact that stigma causes more damage than the disease. The stigma attached to the Hepatitis C virus is insidious. I have been most affected by that. Once, due to my condition, I was asked not to make sandwiches for a children's party but to bring crisps instead.

**4.106** Some relatives expressed sadness that the patient had found it difficult to tell them about their infection and so had, initially, dealt with their diagnosis alone and without their support.

**4.107** A number of patients spoke of being treated differently by healthcare workers due to being infected with HIV and/or Hepatitis C.

**4.108** The husband of one patient, who had died, stated that, in the 1980s, 'HIV' was written in large letters on the front of her medical records. Also around the time when she was admitted to hospital, after the nurse found out that she was HIV-positive, her bed and her locker were moved into a side room. Other patients spoke of their Hepatitis C positive diagnosis being recorded in an obvious manner on their medical notes or on blood samples.

**4.109** A witness, whose son was diagnosed with HIV in the mid-1980s, stated that after this diagnosis her son's treatment in hospital was different. Her son was always kept in isolation. All those treating him wore gowns and gloves. When her son underwent any medical procedures the doctors wore face masks. Patients with haemophilia and HIV were given bright blue, thick bags to return their treatment refuse to the hospital. She stated that, gradually, those families who used these blue bags started to share their experiences with each other. Very quickly these precautions were applied to all haemophilia patients, irrespective of whether they had HIV or not.

**4.110** A patient who is HIV-positive stated that he has been made to feel unclean when he has been in hospital. One doctor would not touch him. In 2010 his GP said to him, 'No one told me you are HIV positive and I have been touching you without gloves on'.

**4.111** A number of patients spoke about healthcare professionals making assumptions about their symptoms being due to alcohol or drug abuse:

When I had to deal with nurses and doctors there was a complete lack of sensitivity to how I had contracted Hepatitis C through a blood transfusion. It was always assumed I had a history of drug taking. I eventually broke down one day and said 'I'm being labelled as a drug user'. The doctors and nurses admitted that this was true and it was a very stressful environment for me to attend but there was no support for a patient like me.

**4.112** Another patient stated that when he attends hospital and undergoes blood tests for other medical conditions, he always tells the staff that he has Hepatitis C. He stated that some of the staff give him 'dirty looks as if I was a needle-sharing junkie or similar' but that their attitude changes significantly when he tells them that he was infected by a blood transfusion.

**4.113** A number of patients stated that when they had undergone medical procedures they were put to the end of the operation list. A patient who underwent a surgical procedure in 2008 stated:

When I was in the ward waiting to go to theatre I reminded the admissions doctor that I had Hepatitis C. Prior to going to theatre I mentioned to a second doctor that I had Hepatitis C. I eventually got to theatre at 4.30pm when someone in the theatre said to me 'You've put the cat amongst the pigeons'. Apparently they had to empty the theatre of all unnecessary equipment and any equipment that couldn't be removed had to be covered in clingfilm because I had Hepatitis C. I eventually got the procedure.

### *Education and work*

**4.114** A few patients or their relatives stated that their education at school, college or university had been detrimentally affected as a result of the viruses. This was mainly due to absence as a result of suffering from the symptoms of the viruses or the side-effects of treatment, caring for a relative or worrying about a relative. As a result some patients were unable to complete the course they had started or did not obtain the qualifications they had hoped to gain. This affected their job prospects and career choice. Some relatives of patients provided statements to the same effect.

**4.115** Some patients stated that their choice of work, including whether they worked full-time or part-time, were employed or self-employed, the type of work they did and where they worked, was affected by their diagnosis with HIV and/or Hepatitis C.

**4.116** A few patients spoke of the difficulty they had obtaining work. One stated that, on numerous occasions, he had attended job interviews at which the prospective employers wished to discuss his medical history. He stated that as soon as he mentioned Hepatitis C these employers believed that he had been injecting illegal drugs. Others were too scared to try to obtain work or a promotion at work as they believed that, in order to do so, they would have to disclose their medical history.

**4.117** A number of patients showed great determination in persisting at work even when they were quite unwell. Notwithstanding this a large number of patients and their relatives had to reduce their working hours, change their role at work (often with a drop in salary),

stop working or sell their successful businesses as a result of the symptoms of the viruses or the side-effects of treatment.

**4.118** This has had numerous consequences for patients and their relatives. The financial impacts are described in paragraphs 4.126–4.139. Many witnesses have suffered stress and worry with regard to their own and their family's finances. Partners and spouses of those unable to work have felt additional responsibility and pressure as the only breadwinner in the family. One witness stated that this weight of responsibility caused her to become anxious about her own health in case she became unable to work. She also felt constantly insecure about the future.

**4.119** A number of patients described how devastated they felt at the loss of a job they had loved or relished. One patient described how he had recently been promoted at work to be a skipper. Due to his symptoms of Hepatitis C and the side-effects of the medication taken to treat it, he had had to stop work and was now unfit for this role. He stated:

This has been totally devastating for me. Your whole life you aspire to be something and then you get there and they take it away from you so easily, you are so easily replaced. My Dad would have been so proud of me being a skipper. I have spent down time crying about this. Also I have never been off work this length of time and it is killing me. I have worked since I left school and have never been idle. I don't do sitting about. It is very hard to fill the day although I like reading.

**4.120** Another patient who has haemophilia and Hepatitis C stated that, when he was young, his GP told his mother that it was unlikely he would ever work due to his haemophilia. This patient was determined to work and, at the age of 17, he found an apprenticeship in an ironmonger's shop. He stated:

It was not the safest working environment but I was so happy and excited to be able to work. I managed fine. Sometimes I worked all day with my knee swelling up due to a bleed and then I would go, by bus, to [...] Hospital in the evening for treatment.

**4.121** He managed to keep working until he was nearly 40 years old when he had to stop due to his symptoms of Hepatitis C.

**4.122** Many patients were reluctant for their employers to find out that they were infected with HIV and/or Hepatitis C for fear of jeopardising their employment or their future career prospects. A patient with HIV and Hepatitis C was asked to provide his employers with a copy of his medical records and to attend an assessment by a doctor after his health took a turn for the worse. He did not wish his employers to know that he was infected with these viruses and so he gave up work. Around this time, he was told by the consultant treating his HIV that he might only have a few more years to live so he should enjoy them. He stated that this was a very stressful time as he and his wife were unsure how they would manage financially.

**4.123** Another patient stated that she was very keen to work and had greater earning potential than her husband. Due to her symptoms of Hepatitis C, she was unfit for work for a period of six months. Before her return to work she was sent for a medical examination by her employers. She stated that there was no confidentiality and she was ostracised once her employers knew that she had Hepatitis C. She was made redundant and her role

was filled by someone from a different office. She found this whole experience 'extremely upsetting'. Another patient stated that she lost her job as a cleaner at a school as she was considered a health and safety risk due to her infection with Hepatitis C. She stated, 'I loved my job and really miss it'.

**4.124** A patient, whose employers are unaware that he has Haemophilia and Hepatitis C, stated that this is 'a huge worry for him'. He is concerned he may become unwell at work and his employers will not know what his underlying conditions are.

**4.125** On the other hand, a number of patients spoke of having confided in colleagues or managers at work about their condition and having been helped by them, for example, by being given less strenuous roles at work.

### *Financial*

**4.126** It is apparent from the witness statements that the financial impact of patients' infections with HIV and/or Hepatitis C has been significant both for the patients and their families.

### **Loss of earnings, pension and savings**

**4.127** A number of patients stated that they had lost substantial earnings as a result of having had to reduce their working hours or stop working altogether due to their symptoms or to the side-effects of treatment. Some had moved to a less well paid role in order to be able to continue working and others had stopped working overtime. A number of patients stated that they had not tried to gain promotion or to obtain a new, better paid job because of their condition and so they were deprived of the opportunity of increasing their earnings.

**4.128** Families of patients who died as a consequence of their infection with one or both of the viruses have been deprived of their relative's financial support. Relatives of those infected also reported having lost earnings as a result of caring for those suffering from the symptoms of the viruses or the side-effects of the treatment, accompanying their family members to hospital appointments or visiting them while they were in-patients in hospital and grieving for their deceased family members after their death.

**4.129** Many patients spoke of having been unable to afford to contribute to a pension or to save. Some had made fewer or lower contributions to their pensions than they had planned due to reduced or no earnings. Many witnesses were understandably anxious about how they would manage financially in the future.

### **Insurance**

**4.130** A number of patients highlighted the difficulties they had faced obtaining life assurance, travel insurance, critical illness cover and private health insurance as a result of their infection with HIV and/or Hepatitis C. A large number of patients were unable to obtain any of these, some having applied to a number of different insurers. Some patients had not tried to obtain any of these policies as they thought that they would be unsuccessful due to their infections with HIV and/or Hepatitis C. Other patients were too embarrassed to apply for such cover. One patient stated that he was worried that a refusal of his application for life insurance would go on 'record against [him] somewhere' or that the refusal would filter back to his mortgage lender.

**4.131** Some patients spoke of having been able to obtain life assurance and travel insurance but at the cost of increased premiums. A number of patients who were over 50 years of age had obtained life assurance cover which did not require medical information.

**4.132** The inability of patients to obtain or increase their life assurance has had a number of consequences for them. A number of patients have been unable to obtain a mortgage or to increase their mortgages. This has resulted in patients renting accommodation instead of buying their own property, remaining in their present home instead of moving to a larger or a more expensive home or obtaining a mortgage without life assurance to cover it. A number of patients stated that their mortgage was in their spouse's or partner's name alone.

**4.133** One patient with HIV and Hepatitis C stated that the only way he was able to obtain a mortgage was with the MacFarlane Trust acting as guarantor.

**4.134** With regard to travel insurance, a number of patients did not disclose their HIV or Hepatitis C diagnosis to insurers when they obtained their cover. Others obtained travel insurance which excluded cover in respect of their HIV and/or Hepatitis C.

**4.135** One patient helped her son buy a car. She applied for insurance to cover the bank loan but was refused this due to having Hepatitis C.

#### **The MacFarlane Trust, the Eileen Trust, the Skipton Fund and the Caxton Foundation**

**4.136** Most of the witnesses had received payments from the MacFarlane Trust, the Eileen Trust or the Skipton Fund.<sup>12</sup> The MacFarlane Trust has made lump sum payments from the late 1980s to those infected and annual discretionary payments thereafter. The payments made by the MacFarlane Trust to an infected individual and dependents, up to about 2011, ranged between £43,500 (where death occurred before or upon establishment of the scheme) to £150,000–£180,000 for those still living. The Eileen Trust, from 20 May 2009, made flat-rate recurrent annual payment of £12,800, with continuing scope for discretionary payments. The range of payment received by patients and dependents from the Eileen Trust, up to about 2011, ranged from £43,500 (where death occurred before or upon establishment of the scheme) to £80,000–£150,000 to those still living.<sup>13</sup> There are three payments currently available from the Skipton Fund. The first-stage payment is £20,000 for those patients who were infected with Hepatitis C through treatment with NHS blood or blood products prior to September 1991, or have acquired it from someone else who received such treatment. The second-stage payment is £50,000 for those who have received the first stage payment and whose Hepatitis C has advanced to the extent that the patient has undergone or is on the waiting list for a liver transplant or the patient has been diagnosed with primary liver cancer or the patient has been assessed as having cirrhosis or the patient has been diagnosed with B-cell non-Hodgkin's lymphoma. The third payment is for those who meet the criteria for the second-stage payment. It is a payment of £14,574 per year. Many patients and their relatives are of the view that the

---

<sup>12</sup> The MacFarlane Trust provides assistance to patients with haemophilia infected with HIV as a result of their treatment with blood products and their families in the United Kingdom ([www.macfarlane.org.uk](http://www.macfarlane.org.uk)). The Eileen Trust was set up to provide financial assistance to those infected with HIV through a blood transfusion or tissue transfer in the form of small regular payments or one off payments to affected persons. The Skipton Fund ([www.skiptonfund.org](http://www.skiptonfund.org)) is a UK-wide ex gratia payment scheme which makes payments to those infected with Hepatitis C through treatment with NHS blood or blood products prior to September 1991 – see paragraph 3.129 of Statistics chapter.

<sup>13</sup> Review of Support available to Individuals infected with Hepatitis C and/or HIV by NHS-supplied blood transfusions or blood products and their dependents as a result of Written Ministerial Statement, Department of Health 'Support for those affected by contaminated blood', Thursday 14 October 2010.

payments they receive from the Skipton Fund are insufficient. A new charity, The Caxton Foundation, also provides financial assistance by way of grants to individuals who have been infected with the Hepatitis C virus as a consequence of receiving NHS treatment using contaminated blood, blood products or tissues or to their relatives.<sup>14</sup>

### **State Benefits**

**4.137** There have been a number of changes to the UK's benefits system during the period of the Inquiry's Terms of Reference and since the witness statements were taken. Infection with HIV and/or Hepatitis C did and does not automatically give rise to an entitlement to state benefits. However, the effects of either virus, whether it be the symptoms, the consequences of these or the consequences of treatment, may result in a person meeting the eligibility criteria for certain benefits. Benefits claimed by patients who gave witness statements to the Inquiry included Income Support, Disability Living Allowance, Incapacity Benefit, Housing Benefit, Council Tax Benefit, Statutory Sick Pay and Pension Credit.

**4.138** A number of patients had to claim benefits as a result of their infection with Hepatitis C and/or HIV. This was difficult for many patients who had taken pride in their work and in being self-sufficient. Many patients described having to claim benefits as degrading and humiliating. A few patients described difficulties in the process of applying for benefits and in obtaining the benefits to which they were entitled. Delays in obtaining benefits caused further financial pressure for some patients.

### **Debt**

**4.139** A number of patients had accrued debt as a result of their infection with HIV and/or Hepatitis C, mainly due to their inability to work. The uncertainty about the future also caused patients and their families to accrue debt: a couple, both diagnosed with Hepatitis C in the early 1990s (the husband was infected with Hepatitis C by his wife) thought that they were going to die. So they gave up work, went on holiday and accrued 'a lot of debt'. Being in debt caused the patients and their respective family great distress and anxiety, particularly as those who were unfit for work had no means to repay their debt. A number of patients were declared bankrupt. Others had their homes and other possessions repossessed. Some patients received financial help from family members in the form of loans or gifts. Many patients were embarrassed by their financial situation.

### ***Additional expenses***

**4.140** Witnesses spoke to having incurred the following additional expenses as a result of their infection with HIV and/or Hepatitis C:

- Travel costs and car parking charges incurred attending hospital appointments or visiting a patient in hospital.
- Prescription charges, the cost of vitamin and mineral supplements and homeopathic remedies.
- Extra heating and fuel costs (many patients described feeling the cold more than they did before), the cost of extra washing and increased bathing.
- Employing a gardener, painter/decorator or person to help with DIY, as they were now unfit to do such chores themselves.
- Increased spending as a symptom of depression.

## CHAPTER 5

### AN EXAMINATION OF THE EFFECTS OF INFECTION WITH HIV ON PATIENTS AND THEIR FAMILIES, INCLUDING TREATMENT

#### Introduction

**5.1** This chapter deals specifically with the evidence given by six witnesses at the Oral Hearings on their own or their relative's infection with HIV.

**5.2** The hearings of evidence on this topic took place on 7, 8, 9, 10, 14, 15, 16 and 24 June 2011. The following patients or relative witnesses<sup>1</sup> gave evidence to the Inquiry in respect of this topic:

1. Christine
2. Amy
3. Frances
4. David
5. Elaine
6. Mark

**5.3** In addition, Professor Clifford Leen, a Consultant Physician at the Regional Infectious Diseases Unit at the Western General Hospital, Edinburgh and Honorary Professor in the Department of Medicine at the University of Edinburgh provided a written report to the Inquiry and gave evidence on this topic.<sup>2</sup> He provided a clinical view on the effects of infection with HIV on patients and their families and gave evidence on treatment for HIV.

#### Christine

**5.4** Christine was 55 years old when she gave evidence to the Inquiry. She is married. At times she was assisted in the evidence she gave by her husband. Christine wished her occupation to remain confidential.<sup>3</sup> Christine's evidence was twofold: firstly in relation to their elder son's infection with HIV and Hepatitis C, and secondly in relation to her own infection with Hepatitis C, both as a result of blood products.<sup>4</sup> For the purposes of this chapter Christine's elder son will be referred to as 'John'. John died aged 20 in the mid-1990s as a result of his infections.

#### *John's diagnosis with Haemophilia A and his treatment*

**5.5** Christine has a family history of haemophilia and as she stated, 'I have lived with it all my life'.<sup>5</sup> Two of her brothers were diagnosed with severe Haemophilia A and she also has a cousin and an uncle with haemophilia.<sup>6</sup> John was born in the mid-1970s. He was born from the breech position and was bruised from the neck down. Despite Christine disclosing her family history to the doctors, John was not diagnosed with haemophilia at that time. When he was about four months old, John developed spontaneous bruising of his right cheek. Christine informed her General Practitioner (GP) about this bruising

---

<sup>1</sup> As detailed in Appendix 1, in order to preserve the witnesses' anonymity, each witness was given a pseudonym.

<sup>2</sup> Professor Leen's report [PEN.012.1044]

<sup>3</sup> Day 28, page 3

<sup>4</sup> Her evidence in relation to the latter is narrated in Chapter 6, *An Examination of the Effects of Infection with Hepatitis C on the Patients and their Families, including Treatment*, paragraphs 6.361–6.371

<sup>5</sup> Day 28, page 15

<sup>6</sup> Ibid, pages 6 and 9

and she believes that the GP thought that they had abused him. He referred John to the Royal Hospital for Sick Children in Glasgow (also known as Yorkhill Hospital) where he was found to have severe Haemophilia A. At the same time Christine was found to be a carrier of Haemophilia A.<sup>7</sup>

**5.6** As a child, John was treated for his haemophilia at Yorkhill Hospital under the care of Dr Anna Pettigrew, a clinical assistant, and as an adult at the Glasgow Royal Infirmary (GRI) under the care of Professor Gordon Lowe. In 1980 the family moved to England for a few months, but returned to Scotland as they considered that the haemophilia care was better at Yorkhill Hospital than the hospital John had attended in England.<sup>8</sup> Initially, and until about 1980, John was treated with cryoprecipitate. Christine and her husband treated their elder son as 'a normal child' and 'we never mollycoddled him'.<sup>9</sup> As a toddler he had more frequent bleeds and so he needed more treatment during this part of his life. Each treatment involved John and one of his parents attending the hospital, being admitted (sometimes after a lengthy wait at the Accident and Emergency Department) and then receiving an infusion of cryoprecipitate, which took up to an hour.<sup>10</sup>

**5.7** In 1980, when John was five years old, he received his first treatment with Factor VIII concentrate. Christine stated 'we thought it was wonderful stuff' as it could be mixed so quickly and injected there and then.<sup>11</sup> John was treated with both Scottish National Blood Transfusion Service (SNBTS) products and American Factor VIII. It was explained to Christine and her husband that the American Factor VIII was much better because, when being made up, it dissolved more easily and it seemed to act more effectively in preventing the bleed from getting any worse.<sup>12</sup> In July 1981 Christine, alongside other parents, was taught to administer Factor VIII to John so that she could give him prophylactic treatment twice a week. This helped reduce the number of bleeds that he had. If he had a breakthrough bleed, Christine gave him further injections of Factor VIII and it was only if he had a particularly bad bleed that he needed to go to the hospital.<sup>13</sup> When he was 14 years old, John learned to give himself Factor VIII and from then on he injected himself.<sup>14</sup> Both Christine and John kept a detailed record of each treatment he had, including the batch number of the Factor VIII used, and the reason for each treatment. Once completed, these records were returned to the hospital.<sup>15</sup>

**5.8** When asked if they were warned of any risks associated with Factor VIII treatment Christine replied:

My husband did ask about risks and they said that, you know, there were risks with everything that was taken. It was just kind of brushed under the carpet when he asked about it.<sup>16</sup>

Christine said in her statement that they were not warned about the risk of infection with HIV or with Hepatitis C.<sup>17</sup> She stated:

---

<sup>7</sup> Ibid, page 5–7

<sup>8</sup> Ibid, pages 9–11

<sup>9</sup> Ibid, page 12

<sup>10</sup> Ibid, pages 11–14

<sup>11</sup> Ibid, page 16

<sup>12</sup> Ibid, page 20

<sup>13</sup> Ibid, pages 21–23; Christine's Witness Statement; a 'breakthrough bleed' happens when bleeding occurs despite prophylaxis treatment.

<sup>14</sup> Day 28, page 24

<sup>15</sup> Ibid, Page 23

<sup>16</sup> Ibid, page 17

<sup>17</sup> Christine's Witness Statement

The doctors were perceived by us to be gods. We trusted them and didn't question the treatment they were giving John. We accepted that they were giving him the best treatment available because that was what they told us.<sup>18</sup>

**5.9** Christine said that she was never warned that there was an increased risk from prophylactic treatment (as opposed to providing treatment in response to actual bleeds). She said that had she been warned of this risk she would never have given her son prophylactic treatment.<sup>19</sup>

**5.10** As Christine stated, what makes 'the whole tragedy' even harder to accept is that mothers and fathers may have given their own children Factor VIII infected with HIV.<sup>20</sup> She stated:

We thought we were doing the best thing for our children by giving them something that allowed them to live a more normal life. All the children in the training group from Yorkhill used the same batch of Factor VIII ... I think that all of the children have now died.<sup>21</sup>

**5.11** Christina Leitch, who worked as a senior social worker at Yorkhill Hospital during the mid-1980s, spoke of the guilt some parents experienced about giving their own children treatment with infected blood products. She also described the guilt some mothers, who were carriers of haemophilia, felt at having passed haemophilia to their children. She stated:

But for many of the parents that was greatly exacerbated by the fact that they were treating their children at home, and although they had not chosen the treatment, had ... no real responsibility for what that treatment had done, I think for many of them it was an incredibly painful thing to look back and consider that, whilst they had been giving their children treatment and believing that that was for the best, in reality that's what had made them ill and which might ultimately cost them their lives. And I think that that was a terrible burden for people to have to live with.<sup>22</sup>

**5.12** Having discovered that she was a carrier of haemophilia, Christine and her husband decided not to have any more children. They adopted a younger boy.<sup>23</sup>

### *John's diagnosis with HIV*

**5.13** In about 1984 or 1985, when John was about nine or ten years old, he and Christine attended one of his regular clinic appointments at Yorkhill Hospital. While they were waiting, Dr Pettigrew came and spoke to them. She apologised for the delay in them being seen by a doctor and explained that there were a lot of children there with HIV and that John was one of those children. Although John gave regular blood samples at his clinic appointments, Christine and her husband were unaware that he had been tested for HIV. Christine cannot remember who she saw after speaking to Dr Pettigrew. She remembers that she was told that the doctors did not know what effect the HIV would have, but that they would closely monitor him. She does not remember being told anything else about the virus or how John had acquired it.<sup>24</sup>

<sup>18</sup> Day 28, page 18

<sup>19</sup> Ibid, page 22

<sup>20</sup> Christine's Witness Statement

<sup>21</sup> Ibid

<sup>22</sup> Day 38, pages 135–136

<sup>23</sup> Ibid, pages 38–39

<sup>24</sup> Ibid, pages 39–43

**5.14** Christine returned home in shock and told her husband the news. As she stated, 'our world crashed down around us'.<sup>25</sup> They had heard that HIV was affecting people in Africa and in the gay community but that was all they knew.<sup>26</sup> John's diagnosis was 'devastating to the family'.<sup>27</sup> Christine and her husband had planned to adopt the sibling of their adopted son but as a result of John's diagnosis with HIV, they abandoned this plan. They were worried that John would feel 'pushed out' if they adopted two natural brothers.<sup>28</sup> They also considered that it was unfair to bring another baby into the house, not knowing what the effects of their elder son's diagnosis were likely to be. She said, 'We had to try and stabilise what we had and not add any more factors into it'.<sup>29</sup>

**5.15** Christine and her husband were not offered any counselling or support at the time of John's diagnosis with HIV. They were encouraged by both their GP and the staff at the hospital to keep his diagnosis with HIV a secret. At the time, Christine and her husband were running their own business and they lived in a small community. Their GP was concerned that they might be ostracised. He advised them that he had sealed John's case notes so that only senior partners in the medical practice could see them. The hospital staff seemed not to know much about HIV, and seemed keen to avoid any panic and to prevent anyone being shunned. The only person Christine and her husband told was one of Christine's brothers as he too was diagnosed with HIV at about the same time as John's diagnosis with it.<sup>30</sup> Christine understands why the doctors thought it was right to keep John's diagnosis a secret but, as she stated:

[The secrecy] was the worst part of our lives. We always had to put on a happy front to the general public. If we could change anything we would not have had the secrecy. Why should we have stigma? We didn't do anything wrong. Other people did something wrong. But they encouraged us to keep quiet about it. The secrecy was like a powder keg.<sup>31</sup>

**5.16** After John's diagnosis with HIV, Christine and her husband felt very isolated. They withdrew into their own family unit. They rarely went out and as a result they lost a lot of friends. When they did go out with friends, they found themselves becoming morose. She stated: 'The only person I could speak to about [John's] HIV was my husband and vice versa. The stress of only being able to speak to each other built up inside us and we took it out on each other'.<sup>32</sup> This caused Christine and her husband to argue with each other. Christine's husband tried to drown out the bad news by drinking too much alcohol. The stigma surrounding HIV was the most difficult aspect for them. Christine stated that they asked themselves constantly why they and John should be stigmatised when they had done nothing wrong.<sup>33</sup> Within a few months of John's diagnosis, Christine and her husband began to realise how serious HIV was from what they read in the newspapers and saw on the television. HIV was known then as the 'gay plague' and it was also linked to drug users in America.<sup>34</sup>

<sup>32</sup> Day 28, page 50; Christine's Witness Statement

<sup>33</sup> Day 28, pages 49–50

<sup>34</sup> Ibid, pages 51–52

**5.17** The Inquiry recovered some newspaper articles from around this time and examples of some of these are:

- Two newspaper articles in February 1985 reported that both fire brigade and ambulance unions had advised their members to avoid direct mouth-to-mouth resuscitation for fear of catching AIDS.<sup>35</sup>
- An article in *The Sun*, dated 19 February 1985, entitled 'Gays put Mrs Mopps in panic on AIDS' reported that cleaners at a theatre where gay actors were performing feared that sweeping up after a show would put them at risk of catching AIDS. The article reported that the cleaners were issued with rubber gloves and bottles of disinfectant.<sup>36</sup>
- In July 1985, the *Birmingham Post* published an article entitled 'Killer AIDS virus has hit 10,000 in Britain'.<sup>37</sup>
- On 3 September 1985 *The Standard* reported that the recording of a television interview with 'two AIDS victims went ahead today using volunteers after some Yorkshire TV staff refused to work in the same studio'.<sup>38</sup>
- In October 1985 a letter was printed in *The Sun* from 'Name and address supplied'. It was headed 'So cruel' and stated 'Your report (*The Sun*, September 23) gives the impression haemophiliacs are spreading AIDS. This is wrong and also cruel because these people suffer enough already. People are born with haemophilia. Their blood doesn't clot and they have injections to keep them alive. Now they are taking a gamble with their lives every time they have an injection. Haemophiliacs have enough to worry about without people spreading these malicious accusations'.<sup>39</sup>
- In July 1986 *The Sun* printed an article entitled 'Swimmers in danger from AIDS'. It reported that an expert, Professor Zuckerman, had warned that people with cuts and bruises could catch AIDS if they go swimming in badly cleaned pools.<sup>40</sup>

**5.18** The above articles are only a very small sample of the large number of reports about HIV which appeared in the press in the mid-1980s. As Dr Patricia Wilkie stated, in the mid-1980s, 'There was never a day when the press didn't have something. And it wasn't just the tabloids, it was also the broadsheets'.<sup>41</sup> Christina Leitch said, 'Some of the adverts on television would have struck fear into most people's hearts. It was a time where there was almost ... hysteria'.<sup>42</sup>

**5.19** About six months after John's diagnosis with HIV in 1984 or 1985, Christina Leitch set up a parents' support group. In her evidence she explained why she did so:

People were terrified that anyone would find out the child had HIV because of the impact that would have on the child and themselves.

So we are talking about parents who are living with an incredibly painful situation as parents and as families, but were also having to deal with this incredible fear

<sup>42</sup> Day 38, page 131

of other people finding out, worried sick about how their children and they would be treated if they did. There were some schools that were anxious about having children with haemophilia and looking for reassurance around those things. It seemed to me that those parents were in an exceptionally difficult situation and unable to talk to anyone very much about it.

There was also a tension that had built up between the families and the hospital. Parents spoke about feeling angry. Sometimes that could be openly expressed and sometimes not, but expressed in different ways. There was a tension at times between the families and the hospital, and I think that was natural and understandable when parents felt that the hospital, the NHS, that was there to treat and care for their children had let them down, was how it was perceived.<sup>43</sup>

**5.20** Ms Leitch stated that, as well as allowing parents to talk to other parents, the support group also allowed couples to talk to one another. She stated:

[P]arents couldn't talk about something like [HIV] when they had children about the house. There was that awful fear that they couldn't even have a conversation within their own homes at the time. So I think the importance of giving them a safe place to talk was quite important and I think the need for that gradually came to an end.<sup>44</sup>

**5.21** Initially, Christine found the parents' group helpful, but there were only a few parents in the group and, once their children started to die, the group quickly broke up.<sup>45</sup>

**5.22** For a few years John remained unaware that he was HIV-positive. He carried on life 'as an active boy who had haemophilia'.<sup>46</sup> He enjoyed sports, particularly playing football and riding his bicycle and he was a member of the Scouts. He later went on to become the youngest Scout leader in Scotland.<sup>47</sup> He was a sociable boy who enjoyed spending time with his friends.

**5.23** Christine and her husband decided not to tell John's teachers about his diagnosis with HIV as they were worried that he would be ostracised, and might have to go to another school. Their worries were based on the difficulties Christine and her husband had, before John started school, persuading the staff that they could admit a boy with severe haemophilia. Prior to John's attendance there, his school had no experience of haemophilia and so Dr Pettigrew and one of the nurses attended to provide staff with information and reassurance about haemophilia. Christine and her husband also promised the school that, if anything happened to John, they would respond immediately. In addition, Christine usually had to accompany John on school trips. After his diagnosis with HIV, Christine was aware that the school had 'blood kits' which contained everything needed to deal with blood spills without the risk of contamination. John had also been taught from a very early age to try to keep his bleeds to himself. In 1987 there was concern about John experiencing a number of nose bleeds at school, and he was referred to a Consultant Ear Nose and Throat (ENT) Surgeon about this.<sup>48</sup>

<sup>46</sup> Ibid, page 52

<sup>47</sup> Ibid, page 115

<sup>48</sup> Ibid, pages 53–56; Excerpts from medical records recovered in respect of John

*John's symptoms of HIV*

**5.24** Until late 1985, John appears to have had no symptoms which could be ascribed to HIV. He attended the hospital regularly for monitoring of his condition. This monitoring included blood tests. In December 1985 it was noted that John had been well, apart from 'recent respiratory tract infections' and poor hearing.<sup>49</sup> The poor hearing was subsequently found to be caused by 'glue ear' and, in 1990, he had grommets inserted to rectify this. In 1986, John had a persistent cough from about October until December.<sup>50</sup> These symptoms may have been attributable to John's infection with HIV or they may have been childhood illnesses which are fairly common in children under 10 years of age. In June 1987 he was referred to a dermatologist due to a large, unsightly wart on his left middle finger which was causing him some discomfort. The dermatologist was advised that John was a 'high risk patient' and from this he surmised that John was HIV-positive.<sup>51</sup> The dermatologist thought that the wart was best left alone. In November 1987 John experienced recurrent tonsillitis, recurrent staphylococcal infections in his ear-lobe and dull hearing in his left ear.<sup>52</sup> Blood tests taken at this time showed that he had a 'healthy' T4/T8 ratio.<sup>53</sup> John was still experiencing recurrent tonsillitis in March 1988. At that time he also had an upper respiratory tract infection. He also continued to experience 'very troublesome' hand warts which were treated with liquid nitrogen. It was known that HIV-infected persons might be more susceptible to hand warts.<sup>54</sup>

**5.25** In April 1989, when John was 14 years old, he was admitted to Yorkhill Hospital with a four-day history of a sore throat, facial pain with facial swelling and purulent (containing pus) nasal discharge. On admission he was found to have a high temperature. Examination and x-rays revealed that he had acute maxillary sinusitis. He was treated for this with antibiotics. Christine stated that the first time John was admitted to Yorkhill Hospital after his diagnosis with HIV he was put into a side room on his own.<sup>55</sup>

He was not allowed to leave the room. Everything in the room was covered in polythene so that he couldn't infect anything. The television and video and all the medical equipment were covered in polythene. The staff would come into the room wearing masks and gowns when they gave him food. They used to put his food into a disposable container before they gave it to him so that it could be thrown away when he had finished eating. One day the home tutor (hospital teacher) dropped a pencil and she refused to pick it up and a member of staff had to go and put gloves on before they picked it up. My son had to grow up like this. He was treated by the NHS as though he was a leper.<sup>56</sup>

**5.26** Christina Leitch described a very similar episode. She stated that she was asked to visit a boy with HIV who had been admitted to hospital the night before. The patient was in a room on his own. She was told that she was expected to wear a disposable gown when she went into his room. Ms Leitch thought this unnecessary and so she refused to wear a gown. When she went into the room, the boys' parents were there. They too had

<sup>55</sup> Day 28, page 63

<sup>56</sup> Christine's Witness Statement; Day 28, pages 63–64

been told to wear gowns. She said that the parents were very upset that their son had been admitted to hospital. She stated:

And they felt that their son was being treated as though he was the carrier of the plague. And he was sitting in bed and a nurse came in completely gowned and she had his lunch on a plate, one of the normal hospital plates, but with a paper plate on top of it, and she told him to hold out his hands and she slid the paper plate onto his hands. And I looked at the paper plate and there were – it was baked beans and mince and mashed potatoes. And I remember looking and thinking “How do you eat that from a paper plate?” And he looked and sort of laughed and said, “This is what it’s been like.” And while he was laughing, it was so obvious that he was deeply hurt by it. It was absolutely horrible and that incident has – it has remained very clearly in my mind for a very long time.<sup>57</sup>

**5.27** Christine used to take meals into the hospital for John so that ‘he could have his meal as a normal person rather than eating it out of this disposable dish’.<sup>58</sup> Christine saw other children with haemophilia being treated in the same way. Unsurprisingly, the parents complained about the way their children were being treated. The staff said that they were trying to be safe. At this time John was still unaware that he was HIV-positive. Christine does not know how he felt about this treatment, stating that John ‘was a boy that just took everything in his stride’.<sup>59</sup>

### *John is told of his diagnosis*

**5.28** In 1989, when John was 14 years old, Christine and her husband made the important decision to tell him about his HIV status. By this time they had known that John was infected with HIV for about four or five years. During this period they had been told by someone at the hospital that John had been infected by Factor VIII. Christine cannot remember when they were told this.<sup>60</sup> The reason Christine and her husband decided to tell their elder son that he was HIV-positive was that they were concerned that he might become sexually active. Christine’s husband discussed it with the doctors at one of John’s clinic appointments and they agreed that he was at an age where, possibly, he should be told. The doctors offered to tell John but Christine’s husband decided that they would tell him, as a family, at home. They were not given any advice by the hospital about how to tell him. Christine and her husband did not know any more about the virus than what they had read or seen on the television. They did not know what the long-term prognosis was for John. Christine’s husband explained to John that he had contracted HIV from infected Factor VIII. John burst into tears and asked when he was going to die.<sup>61</sup> John had heard about HIV by this time but all he knew about it was that it was ‘a gay plague’.<sup>62</sup> After being told his diagnosis, John was very quiet and withdrawn for a while. Christine and her husband tried to encourage him, as much as they could, to carry on as normal.<sup>63</sup> Christine stated that John then ‘pulled himself together and did cope, and just got on with his life for a long time, which was hard for a vulnerable 14-year old’.<sup>64</sup> As far as Christine

<sup>64</sup> *Ibid*, page 65

is aware, John never told anyone that he was HIV-positive.<sup>65</sup> There was no support group for the children. Christine stated that if the HIV-positive children discussed their diagnosis with each other, they kept it to themselves and never told their parents that they did so.<sup>66</sup>

**5.29** Christine recalled that, in 1989, John took part in a clinical trial with a drug intended to fight infections of the lung. This is likely to have been a trial of Co-trimoxazole to prevent pneumocystis carinii pneumonia (PCP).<sup>67</sup> Christine does not know if John received the placebo or the drug during this trial.<sup>68</sup> In about 1990 joint clinics were started at Yorkhill Hospital which were attended by a doctor from Ruchill Hospital as well as a doctor from Yorkhill Hospital. At that time, Ruchill Hospital treated adults and children with HIV and AIDS. At a joint clinic in April 1990, John was noted to be in excellent health and asymptomatic in respect of his HIV infection. His CD4 cells remained at 'an acceptable level of 580 cells/mm<sup>3</sup>' with a CD8 count of 807 cells/mm<sup>3</sup>.<sup>69</sup>

**5.30** The CD4 cell count test became available in the mid-1980s. This was one of the earliest tests available to assess the status of the virus. In the early days of treatment it was one of a number of factors considered by clinicians when deciding when to treat a patient. The other factors were the toxicity of the early drugs to treat HIV, resistance to the treatment, and treatment fatigue versus the benefit of treatment over a long period of time. Clinicians' knowledge and understanding of the significance of a CD4 cell count was not as good in the mid-1980s as it is now. It evolved over the years and the CD4 cell count became one of the best measures of assessing the progression of the infection.<sup>70</sup> Now, the *British HIV Association guidelines for the treatment of HIV-1-infected adults with antiretroviral therapy 2008* recommend that treatment should be started in all patients with a CD4 count of fewer than 350 cells/uL (or cells/mm<sup>3</sup>) and in those patients with certain clinical symptoms.<sup>71</sup>

**5.31** John's doctors considered that there was no indication for antiretroviral therapy but stated that they would continue to monitor him closely. In October 1990, John experienced an episode of discharge from his left ear. At this time, Christine told the doctors that she was concerned that John was experiencing night sweats. Although he was telling her he was not having such episodes, he was putting his sheets out very regularly for washing. John was very private about such matters and Christine did not like to press him about this.<sup>72</sup> She stated:

It was a difficult balance. We had a relationship that if anything really worried him, we knew he would come and talk to us but we never pushed him on it. We asked him; if he denied it that was fine, even though we had other ideas on it.<sup>73</sup>

<sup>65</sup> Ibid, page 67

<sup>66</sup> Ibid, page 69

<sup>67</sup> Co-trimoxazole was used by clinicians to treat patients with PCP before HIV was identified, Professor Leen – Day 33, page 38. After PCP was diagnosed in the first patients with AIDS in the early 1980s, Co-trimoxazole was prescribed for patients with HIV as a prophylactic treatment, Professor Leen – Day 33, page 34

<sup>72</sup> Day 28, pages 74–75

<sup>73</sup> Ibid, page 75

**5.32** When checked in September 1990 John's CD4 cell count was 380 cells/mm<sup>3</sup>. The issue of whether to start treatment with Zidovudine (also known as AZT) was discussed with Christine and John, and it was decided at that time not to commence this treatment. At the time it was difficult to know when to start therapy as there was a body of opinion that Zidovudine therapy should be started when the CD4 cell count fell below 500 cells/mm<sup>3</sup>. However, that was not the policy of Ruchill Hospital. Although staff at the hospital started therapy with Zidovudine earlier than they had done before, they were concerned about the resistant strains of the virus.<sup>74</sup> Christine stated that they were told that if John started Zidovudine treatment, he would have to continue with it. If he subsequently stopped the treatment the virus would become resistant to the drugs and he would be unable to use that treatment again. Christine stated that it was John's decision when to start treatment and she and her husband supported his decision. On hearing that it was not 'absolutely imperative' that he start treatment, John decided not to at that time.<sup>75</sup>

**5.33** The development of antiretroviral therapy for HIV is discussed in Chapter 8, *Knowledge of HIV/AIDS Now*, paragraphs 8.35–8.40. In 1986 and 1987 there was uncertainty about the effectiveness of Zidovudine as a treatment for HIV. It caused a number of side-effects and it required to be taken every four hours. It was difficult for clinicians, like those treating John, to decide when to treat a patient who was still asymptomatic or very mildly symptomatic. Patients who were treated in the 1980s and early 1990s received very little support in adhering to their medication. Understandably, there was, and there continues to be, difficulty persuading children and teenagers, in particular, to take such medication.<sup>76</sup>

**5.34** In the early days of treatment with Zidovudine, there was bad publicity surrounding it. A television programme showed people that it was a toxic medication and reported that clinicians were being rushed into prescribing it. As Zidovudine was not particularly effective, patients sometimes saw their friends taking it and dying and so they associated the cause of the death with the drug. This caused patients to resist being prescribed Zidovudine.<sup>77</sup>

### *John's treatment with Zidovudine*

**5.35** In early 1991, when John was 15 years old, he started treatment with Zidovudine. It was noted that he remained 'in general good health' but that his CD4 count had fallen to 200–300 cells/mm<sup>3</sup> on the last two occasions it had been measured.<sup>78</sup> He was also prescribed nebulised Pentamidine as prophylactic treatment against PCP. The Zidovudine treatment consisted of tablets which John had to take five times a day. He had to take one of the tablets at school, but managed this without any problem. Christine and her husband encouraged John to keep taking the medication and, on the odd occasion, he needed reminding to do so.<sup>79</sup>

**5.36** In September 1991 John was noted to be very well apart from a recent upper respiratory tract infection. He had a number of lesions and red patches on the roof of his mouth which were thought to be viral in nature. His CD4 cell count remained stable, being 217 cells/mm<sup>3</sup>.<sup>80</sup> Between September and December 1991, John had a sore throat.

<sup>74</sup> Ibid, page 75; Excerpts from medical records recovered in respect of John; Chapter 8, *Knowledge of HIV/AIDS Now*, para 8.37

<sup>75</sup> Day 28, pages 76–77

<sup>76</sup> Professor Leen – Day 33, pages 62–63

<sup>77</sup> Ibid, pages 23–24

<sup>78</sup> Day 28, page 77; Excerpts from medical records recovered in respect of John

<sup>79</sup> Day 28, pages 78–79

<sup>80</sup> Ibid, pages 79–80

His appetite reduced and he lost about two and a half kilograms in weight. His recent CD4 count was 127 cells/mm<sup>3</sup> and Dr Gibson, consultant haematologist, was of the view that this, together with John's weight loss, was 'a rather concerning feature'.<sup>81</sup> Dr Gibson was concerned that if John's HIV disease was progressing it might produce more marrow toxicity related to his Zidovudine treatment and so she reduced his dose of Dapsone<sup>82</sup> (which John was by this time being prescribed to prevent PCP) to minimise the combined marrow suppressive effect of these drugs.

### *John's treatment at the Glasgow Royal Infirmary*

**5.37** In December 1991, as John was almost 17 years old, he was referred to adult services and to Professor Lowe, a consultant physician, Haemophilia and Thrombosis Unit at the GRI. In her referral letter Dr Gibson noted that John was positive for the antibody to Hepatitis C.<sup>83</sup> Christine stated that she did not know until after John died that he had Hepatitis C. She does not think that John knew either as she is sure he would have told them if he had known. After John died, Christine asked a nurse if John had contracted Hepatitis C. The nurse replied in 'a matter of fact, off the cuff' remark, 'Oh yes, all of our boys have got it'.<sup>84</sup> In her referral letter Dr Gibson stated that John was 'a delightful young man' and that she would be anxious to hear how he progressed.<sup>85</sup>

**5.38** John attended his first appointment at the GRI with his mother on 22 January 1992. There they met Professor Lowe and a doctor from the Infectious Disease Department at Ruchill Hospital. They also met the unit staff including nursing staff, physiotherapy staff and the medical social worker. John was noted to have a small boil on his right chin from shaving, wax in his ears, bilateral increase in tonsils and a few patches of redness on his palate. It was planned that he would continue to attend for monthly review.<sup>86</sup> In June 1992 he was noted to be experiencing sensitivity to light affecting his right eye. He was referred to an ophthalmology doctor who specialised in ocular disease in immune-compromised patients.<sup>87</sup> The doctor concluded that there was no evidence of ocular disease and he considered John's symptoms might be stress related.<sup>88</sup> Christine thought that John's eye problems were due to spending too long in front of a computer.<sup>89</sup>

**5.39** That summer John went on holiday with his family to Spain. During this holiday he was bothered with a cough which produced green spit for about two weeks. He also suffered from diarrhoea and developed a nose bleed which caused him to cough up some blood. When he attended his clinic appointment on 21 July 1992 he was noted to have some seborrhoeic dermatitis (an inflammatory skin condition) on his face.<sup>90</sup> Christine took John to a Chinese Herbal doctor who concluded that his dermatitis was caused by a reaction to the ingredients of food from a burger chain which John was eating regularly at that time. The dermatitis cleared up when he stopped eating this food. With regard to his chest symptoms, John underwent a chest x-ray and tests revealed that there was a heavy growth of haemophilus influenzae (a bacterium associated with acute and chronic respiratory infections). He was prescribed antibiotics for this. In August

<sup>81</sup> Ibid, page 80; Excerpts from medical records recovered in respect of John

<sup>82</sup> Dapsone was a second-line treatment for PCP

<sup>83</sup> A blood test dated 15 June 1990 confirmed that John was positive for the antibody to the Hepatitis C virus

<sup>88</sup> Ibid

<sup>89</sup> Day 28, page 85

<sup>90</sup> Ibid, page 85; Excerpts from medical records recovered in respect of John

1992 John experienced a recurrence of sinusitis.<sup>91</sup> There was some improvement in his condition but he continued to be troubled by a cough. On one occasion his cough was blood-stained. On 11 September 1992 John was admitted to the GRI with lower left lobe pneumonia. He gave a history of an increasingly severe cough productive of green sputum, breathlessness principally on exertion, lethargy, malaise and occasional vomiting after paroxysms of coughing. It was thought that his infection was bacterial. He was prescribed antibiotics and was discharged from hospital when his condition improved.<sup>92</sup> In October 1992, John was admitted to hospital briefly and was prescribed further antibiotics as a sample once again showed haemophilus influenzae, and also candida albicans (a fungus which causes yeast infection). At this time, John also had facial folliculitis (inflammation of hair follicles causing rash, itch and pimples) and fungal infections of his thumbnails.<sup>93</sup> Christine described John's nails as looking as if they were rotting. John was referred to a dermatologist, who noted that, in addition to the fungal infections of his nails, John had developed a rash on both his scrotum and face. He was prescribed Terbinafine (an antifungal treatment). It was recommended that John undergo regular liver function tests while being on this medication.<sup>94</sup> On 12 November John was admitted to hospital with a haemophilus influenzae chest infection. Once again he was treated with antibiotics and was discharged home five days later.<sup>95</sup> Around this time, he underwent hyperbaric oxygen treatment which caused a great improvement in his chest symptoms.<sup>96</sup>

**5.40** John continued to suffer from a cough and chest symptoms. He also suffered from a right middle-ear infection. In March 1993 he was prescribed Zalcitabine in addition to Zidovudine.<sup>97</sup> According to a letter from a consultant physician at Ruchill Hospital to Professor Lowe, Zalcitabine was 'released on a compassionate basis' for John.<sup>98</sup>

**5.41** John was admitted to hospital on two separate occasions towards the end of March 1993. Both times he was admitted due to coughing up blood following bouts of coughing. During the first admission he was treated with high dose Factor VIII 12-hourly and, after his condition stabilised, he was discharged home the next day. The second time he was admitted to hospital, he had a high temperature. He underwent a bronchoscopy which revealed bronchiectasis (damage to the lung tissue leading to a build-up of mucus, which in turn makes the airways more prone to infection). John was prescribed intravenous antibiotics, and when his condition improved, after about four days, he was discharged home. During this admission, it became apparent that he had not been taking his anti-viral medication regularly. Prior to his discharge Christine spoke with Professor Lowe. He stressed to Christine how important it was that John keep taking his medication although he appreciated that, as he was an adult, it was harder for them to enforce this.<sup>99</sup>

**5.42** Christine and her husband had been unaware that John had stopped taking his medication. It had been emphasised to him that he needed to take his medication regularly, and that once he had started taking it he would need to keep taking it, otherwise the HIV

<sup>98</sup> Day 28, page 89; Excerpts from medical records recovered in respect of John; the use of drugs being released on a compassionate basis may also be referred to as 'on a named patient basis'. 'Named patient basis' meant that, if a clinician considered that a patient would benefit from a medication prior to it being licensed, the clinician could request access to the medication for this patient from the manufacturers.

<sup>99</sup> Day 28, pages 92–93; Excerpts from medical records recovered in respect of John

symptoms would return with 'a vengeance'.<sup>100</sup> Despite this advice, John stopped taking the antiviral medication. The medication made him feel tired and sick. Christine and her husband often asked John if he had taken his medication and he told them that he had, when they now know he had not. She believes that John did not tell them he had stopped his medication as he could see how much stress they were under and did not wish to bother them.<sup>101</sup>

**5.43** In April 1993, John was suffering from nausea. Professor Lowe reduced his dose of Zidovudine and prescribed him Maxolon (an antiemetic medication) for this. In addition to these medications, he continued to be prescribed Zalcitabine and Co-trimoxazole. John continued to suffer from a regular cough, a rash on the right hand side of his face and neck and a fungal infection of his thumbnails.<sup>102</sup>

**5.44** In June 1993, John left school aged 18 years. Despite all his absences from school due to hospital admissions and appointments, he successfully obtained the exam results he needed to go to college to study an HNC in computing as he had hoped to do.<sup>103</sup> Christine stated that at school John was 'quite switched on' and, with the help of a friend who brought work home for him, he always made the effort to catch up on schoolwork that he had missed.<sup>104</sup> One summer, John went to a summer camp in the USA with other boys with haemophilia from Yorkhill Hospital. They were accompanied by staff from the hospital. The trip was partly funded by the Round Table, a local charity in Glasgow, and by the MacFarlane Trust.<sup>105</sup>

**5.45** In the summer of 1993 John went on holiday for a week to Europe with the Scouting group. He was unwell while he was there. When he attended a clinic appointment that August, he had marked facial dermatitis on the right side, looked tired and pale and had lost about 14lbs in weight. He continued to have chest problems, with a productive cough and purulent sputum. He was noted to have crepitus (crackling) and rhonchi (a coarse rattling sound) in his left lung. He had a lesion on his tongue. Dr Kennedy, the Consultant who saw John at this appointment, wrote to John's GP: 'I did not like the look of [John] today.' Dr Kennedy prescribed him a course of Erythromycin (an antibiotic used to treat bacterial infections).<sup>106</sup>

**5.46** In about August 1993 John started the computing course at college. His health stabilised for a while and he gained some weight. He also obtained part-time work delivering meals for a restaurant three or four nights a week. He thoroughly enjoyed this work, but he found it tiring and it took its toll on him.<sup>107</sup> In December 1993 John went with the family on holiday to Spain. This was the last family holiday they had together. John had a cough, diarrhoea and a nose bleed while they were away but Christine stated that, despite this, he had a good time.<sup>108</sup> On his return he was prescribed a course of antibiotics for chest symptoms and mouth ulcers. The treatment improved both.<sup>109</sup>

<sup>108</sup> Day 28, pages 98–99

<sup>109</sup> Ibid, page 99; Excerpts from medical records recovered in respect of John

**5.47** On 24 May 1994, John was admitted to the GRI as a result of gastrointestinal haemorrhage. On admission he had a two-day history of vomiting 'coffee ground fluid' (indicative of digested blood in the stomach) associated with general weakness, lack of energy, fever and an intermittent cough. His haemoglobin was found to be low, and he was transfused with three units of packed cells and Factor VIII. He was given a course of Magnapen (a penicillin-type antibiotic used to treat bacterial infections) and oral iron. He underwent an isotope red blood cell scan which showed bleeding in the ascending colon. He also underwent a colonoscopy. He was discharged on 22 June. At discharge, his haemoglobin had increased. He suffered a cough for three days with greenish spit, and was prescribed a further course of Amoxicillin.<sup>110</sup>

**5.48** After completing his computer course, John went to work full-time for a family-run catering business in their office. He went to work no matter how ill he felt.<sup>111</sup> He was keen to obtain a second job working part-time with a retail company. Christine and her husband were concerned about how tired John became working in the one job. They sat down with him and discussed the pros and cons of a second job, particularly with regard to his tiredness. John then agreed not to pursue the second job. It was apparent from Christine's evidence that she and her husband took great care to allow their elder son to lead as full and as independent a life as he wished which, in the circumstances, must have been difficult. She stated:

[W]e had to let him live his life. We didn't know how long it was going to last. We knew it would eventually – we weren't sure, we didn't know, so he had to make his own decisions. And he did appreciate our comments, when we felt we had to intervene, that we weren't nagging, that it was just constructive.<sup>112</sup>

**5.49** John managed to work at the catering business for three months. The owners of the business knew that he had haemophilia, but did not know that he had HIV. They were very supportive of him. There were times when they telephoned Christine's husband and asked him to come to collect John as he was so unwell. At times, Christine's husband had to collect him from work and take him straight to the hospital. John's employers were very upset when they had to let him go due to his ill-health.<sup>113</sup> One can only imagine how disappointed John must have felt.

**5.50** In the summer of 1994 John stopped taking his antiretroviral medication again, and his prophylactic Co-trimoxazole. Christine stated that, once again, he became 'fed up with having to take tablets all the time and how ill they were making him feel'<sup>114</sup> and 'the side effects were quite straining on him'.<sup>115</sup> He was trying to work, trying to just be normal and he felt the side-effects were just bringing him down. She stated:

He was fed up. I do not think that he thought it through properly when he came off the medication. We could not keep track because when he became an adult patient we lost control of managing his care. The hospital would not tell us anything. We could not search his room and count the tablets. He had made up his mind. He was very fit and went to the gym. Maybe he thought he would survive without medication. Perhaps he thought he was indestructible.<sup>116</sup>

<sup>114</sup> Ibid, page 102

<sup>115</sup> Ibid, page 91

<sup>116</sup> Ibid, page 92

**5.51** John's condition continued to deteriorate. He suffered from repeated chest infections.<sup>117</sup> In about October or November 1994 he was admitted to Ruchill Hospital with PCP. This was successfully treated. In November John was still slightly wheezy, had a rash on his back, oral candidiasis (thrush) and a fungal skin eruption over his shoulder.

**5.52** In January 1995 John was admitted to Ruchill Hospital due to vomiting and a joint bleed. He underwent a gastroscopy and was found to have developed two ulcers.<sup>118</sup> His lungs were badly damaged. John was told that the ulcers could be treated. A few hours after the gastroscopy, he became paralysed and he could only move his head. The doctors did not know what had caused this. By this time he had lost a lot of weight and was unable to do anything for himself. He felt degraded. The doctors told Christine and her husband that John did not have long to live and so, on 13 February, they took him home.<sup>119</sup>

**5.53** At home, Christine and her husband made up a bedroom for John downstairs. Initially they tried to care for him themselves, but it became impossible for them to do so. He needed assistance with everything. Ruchill Hospital organised nurses to care for John overnight so that Christine and her husband were able to sleep. The only thing John asked them to do was to take him to the toilet during the night. He used a commode, and it took two people to lift him onto it so as not to hurt him.<sup>120</sup>

**5.54** John started having nose bleeds. Christine telephoned the GRI for help, and three days later someone came to the house to see him. This person cauterised the bleed, but by this stage John had blood in his lungs. He developed a further lung infection. He needed oxygen, and this was provided for him at their home. On 7 March 1995 John died while holding his parents' hands. Before dying he said, 'Dad, just leave me, I'm ok' and he told his parents that he loved them.<sup>121</sup>

**5.55** About two days after John's death, the possibility of a post mortem being carried out was raised with Christine and her husband. Initially they were not keen on this, but after discussions with the hospital social worker, they agreed to it in the hope that the findings might assist other patients with HIV. There was another child with similar symptoms to John and they hoped to help this child. Six months later Christine and her husband went to Ruchill Hospital for the post mortem results. They were told that the post mortem report had been mislaid. They returned at least two further times to obtain the result, but each time they were again told it was mislaid. After Christine gave evidence the Inquiry investigated this matter further. In September 2011 the Inquiry obtained a copy of the post mortem result for John, and it was then forwarded on to Christine. The post mortem concluded that John died as a result of pneumococcal pneumonia and bronchiectasis.<sup>122</sup>

**5.56** John's funeral was attended by family, friends and representatives of the Scout Association. Nobody at the funeral knew that he had died of AIDS. They understood that he had died of pneumonia. In 1996 both Christine and her husband were tested for HIV, and were found to be negative. A few times Christine had received a needle stick injury whilst giving John his medication.

<sup>122</sup> Post mortem report for John

**5.57** Christine and her husband were offered counselling by the MacFarlane Trust but she stated, 'it is not easy to talk to a stranger in a hotel'.<sup>123</sup> Their GP told them that they were the best counsellors for each other, but Christine feels that that advice perpetuated the secrecy. With the benefit of hindsight Christine feels that they were wrong not to accept counselling; especially in respect of their younger son. She stated that they had 'guilt trips' about how they had handled things.<sup>124</sup> She stated, 'Even now I burst into tears, when I think about the past, which may not have happened if we'd had someone to talk to at the time for advice'.<sup>125</sup> Christine and her husband subsequently attended five bereavement weekends organised by the MacFarlane Trust. Christine described these as weekends 'without any secrecy'.<sup>126</sup> She found it very helpful to meet others in the same situation, and to speak openly.

**5.58** At the time of John's death, his brother was 14 years old. He was unaware that his older brother had HIV, and when John died, he was told that he had died of pneumonia. Christine and her husband told their younger son when he was in his 20s that his older brother had died as a result of HIV. With hindsight, Christine believes that they should have told him the truth sooner. Their younger son has been deeply affected by his brother's death and has been troubled ever since. He suffered from acute depression during his teenage years. He continues to grieve for his brother. He is now an alcoholic.<sup>127</sup>

**5.59** In 1997 when Christine's younger son joined the Army, Christine and her husband were unable to envisage their future in a house without children and so they became foster parents. Since then they have fostered three children long term for about six or seven years, and cared for other children in between at weekends and overnight.<sup>128</sup>

**5.60** About a week before John died, Christine and her husband discovered that a girlfriend of John was pregnant. Christine's husband had spoken to John about this and he told his father that he had had a sexual relationship with her, but that he had practised safe sex. This girlfriend came to John's funeral. She later had a son. Christine and her husband built up a relationship with her. She had an HIV test which was negative. Eventually Christine and her husband started to see their grandson and he started to visit them regularly. He is now a teenager. He has his own room in their home and comes on holiday with them. He has the same mannerisms as John. Christine stated, 'He is a great wee lad and it makes my day when I see him'.<sup>129</sup> She believes that he and their foster children have helped them cope with their immense grief at the loss of John.

### *Financial impacts of John's infection with HIV*

**5.61** In the early 1990s Christine 'tried to top up my life insurance policy'. Her GP refused to sign the application form to enable her to do this. She believes that the GP was concerned that she too had acquired HIV. Eventually the matter was cleared up but it was 'a very long, drawn-out affair'.<sup>130</sup>

**5.62** John received two payments from the MacFarlane Trust. He received the first payment of £20,000 in 1990 when he was 15 years old and the second payment of £20,000 in

1991. In order to receive the money, John had to sign a waiver saying that he would not take any further action against the UK Government in respect of contracting HIV. He had to sign this form at a solicitor's office and neither Christine nor her husband was allowed to be present when he signed the waiver. The money was to be used to buy him a car. The rest of the money was put aside for John and was used to buy something that he wanted or needed. John wanted his parents to use the money. John also received monthly payments from the MacFarlane Trust while he was alive. Christine cannot remember how much they were. Christine's grandson now receives £250 a month from the MacFarlane Trust and will continue to do so while he is in full-time education.<sup>131</sup>

## Amy

**5.63** Amy was 49 years old when she gave evidence to the Inquiry. Amy is separated and has two sons. She gave evidence about her elder son's infection with HIV from a blood transfusion. For the purposes of this chapter Amy's elder son will be referred to as 'Luke'.

### *Luke's blood transfusion*

**5.64** Luke was born in Ninewells Hospital, Dundee in the mid-1980s. He was born at 42 weeks' gestation by emergency caesarean section due to foetal distress. At section, the fluid was blood stained which was suggestive of possible placental abruption (condition in which the placenta partially or completely separates from the lining of the uterus). At birth, Luke was seriously ill. He was 'rather flat with an Apgar score of 1 at one minute'.<sup>132</sup> He was ventilated and admitted to the Special Baby Unit. In the Unit he was noted to have signs suggestive of cerebral irritation and convulsions. An ultrasound of the skull suggested cerebral oedema (excessive accumulation of fluid in the brain). He was managed with ventilation, fluid restriction and medication. He was given a loading dose of Phenobarbitone, an anticonvulsant medication. Due to low blood pressure, he received a transfusion of plasma protein solution. He was also given fresh frozen plasma. He developed a bacterial infection and then renal failure. During this time, Amy and her husband were aware how seriously ill Luke was. They were told that he was living only on a 'day-to-day' basis.<sup>133</sup> His condition improved with treatment and, 16 days after he was born, he was discharged home on medication. He was provided with a heart monitor for use when he slept or was in the pram at home.<sup>134</sup>

**5.65** Luke continued to recover at home. At a review appointment in November 1985, he was noted to be making excellent progress and Amy had no concerns about him. He was smiling, laughing, gurgling normally and was alert and lively.<sup>135</sup>

### *Luke's diagnosis with HIV*

**5.66** Some months after Luke's birth, his GP arrived unexpectedly at their home. Amy was there with her mother and Luke. The GP explained to Amy that Luke had been infected with HIV from the blood he had received at birth.<sup>136</sup> Amy was numb with shock and she

<sup>131</sup> Day 28, pages 110–111

<sup>132</sup> Day 29, pages 6–7; Excerpts from medical records recovered in respect of Luke; the Apgar test is a test to measure the vital signs of a baby at birth. Out of a potential score of 10, 7–10 is a normal score.

<sup>133</sup> Day 29, page 10

<sup>134</sup> *Ibid*, page 8

<sup>135</sup> *Ibid*, page 9; Excerpts from medical records recovered in respect of Luke

<sup>136</sup> The donor of the FFP which Luke had received was found to be infected when he subsequently donated blood again in 1986. Retrospective testing then showed that his previous donation was infected too. Excerpts from medical records recovered in respect of Luke; Day 29, pages 13–14

could not believe what she was hearing.<sup>137</sup> She found the news 'really devastating'.<sup>138</sup> At that time the fact that Rock Hudson had AIDS was a big news story and that was what Amy knew about HIV. Her GP did give her some information about HIV but Amy cannot now remember what he told her. She remembers that he told her that Luke should attend hospital appointments. The GP then left the house, and Amy had to tell her husband when he came home from work. The news was particularly devastating for them given all they had been through since Luke's birth. She stated that, having watched their son improve after his difficult birth, they reverted to being concerned for his future. They were aware that medications for HIV were not good at that time.<sup>139</sup>

**5.67** Luke's GP referred him to a Consultant Paediatrician at Ninewells Hospital. In his letter of referral he wrote that Amy and her husband were 'naturally ... upset and anxious about the future'.<sup>140</sup> At Luke's first appointment with the Consultant Paediatrician on 1 April 1986 he was tested for HIV and found to be positive.<sup>141</sup> Amy and her husband were told the result of this test at the next hospital appointment in May. The doctor had the impression that they had accepted Luke's diagnosis 'extremely well' and had 'a realistic understanding of the problems'.<sup>142</sup> Amy remembers that, around this time, they were advised to be careful to avoid secondary infection. They were told to use gloves and bleach.<sup>143</sup>

### *Luke's early childhood*

**5.68** From May 1986 onwards Luke attended regular appointments at the hospital. These were between three to six months apart depending on his state of health.<sup>144</sup> At each appointment, Luke underwent blood tests and his glands and general welfare were checked. Amy usually took him to these appointments by bus. She had to take time off work to do so.<sup>145</sup>

**5.69** When Luke was between two and three years of age he was diagnosed with a hearing impairment affecting both ears. Before this, he had become increasingly frustrated and had difficulty with his speech. When he was about three years old, Luke had grommets inserted. He was put to the end of the operation list due to being HIV-positive. When he was five years old he was given hearing aids. Amy was told that these hearing problems were a result of the difficulties he experienced immediately after his birth.<sup>146</sup>

**5.70** Amy remembers that, in the early days after Luke's diagnosis with HIV, when they attended hospital they were sometimes put in a room on their own. This made her feel isolated. On one occasion, a doctor blamed Amy for having given HIV to her elder son as he had assumed that Luke had acquired the virus from Amy's breast milk.<sup>147</sup>

**5.71** When Luke was three years old, he frequently woke up during the night and often at that time was found to be sweating excessively. Amy stated that when her elder son

<sup>146</sup> Ibid, pages 17–20; Amy's Witness Statement

<sup>147</sup> Day 29, page 19

sweated 'his blankets and everything would be absolutely soaking'.<sup>148</sup> He had swollen lymph nodes on his neck and in his armpits and was thrombocytopenic (abnormally low number of platelets). As a result of this he bruised easily. At a clinic appointment in July 1988 the possibility of Luke being treated with Zidovudine, were his condition to deteriorate, was discussed with Amy.<sup>149</sup> She was told that Zidovudine had already been introduced as treatment for a few children, and was well tolerated by them. Amy was aware that Zidovudine was a new treatment for HIV and so the side-effects of it were unknown. She thought that the doctors would effectively be testing the treatment on Luke. Notwithstanding this, she was keen to try whatever might help him.<sup>150</sup>

**5.72** In July 1989 Luke's care was transferred to Dr Tarnow-Mordi, a Consultant Paediatrician. At that time he continued to suffer from thrombocytopenia, swollen glands in his neck and armpit and enlarged lymph nodes in the groin area. In about August 1989 Luke started nursery. Amy was advised by the hospital that there was no need to inform the nursery of his HIV status, since any bleeding accident should be treated uniformly for all children.<sup>151</sup>

### *Luke's treatment with Zidovudine and immunoglobulin*

**5.73** Towards the end of 1989, when Luke was four years old, he started treatment with Zidovudine. Luke had been keeping well. Amy stated that he started treatment to sustain a better chance of living, and to improve his immune system. After starting treatment his night sweats improved slightly, and occurred only once or twice a week. He was noted to have new enlarged submandibular glands (salivary glands situated beneath the floor of the mouth).<sup>152</sup>

**5.74** Luke did not like the taste of Zidovudine and he started refusing to take it. Three months after he had started the treatment, he had lost weight. His appetite was poor and he continued to have night sweats. His submandibular lymphadenopathy (swollen lymph nodes beneath floor of the mouth) was a little more marked.<sup>153</sup> With the encouragement of a star chart, Luke was persuaded to keep taking his medication and a month later he had regained some weight, and his lymph nodes remained unchanged.<sup>154</sup>

**5.75** About this time, Dr Tarnow-Mordi put Amy in touch with another family with a similarly affected child as he thought that it would be helpful for them to speak to someone in a similar situation. Amy spoke to the mother in this family. Due to the stigma attached to the virus, Amy and her husband only told their siblings and their parents of Luke's diagnosis with HIV. They did not tell any of their friends or their aunts and uncles. They did not wish their elder son to be isolated. To this day only their immediate family know that he is HIV-positive. Amy felt that the only people she could speak to about Luke's condition were her mother and her sisters. If she spoke to them about it, she felt she placed a burden on them as they were unable to speak to anyone about it. Amy found this 'hard'.<sup>155</sup>

<sup>148</sup> Ibid, page 20

<sup>149</sup> Ibid, pages 20–21; Excerpts from medical records recovered in respect of Luke

<sup>150</sup> Day 29, page 22

<sup>151</sup> Excerpts from medical records recovered in respect of Luke

<sup>152</sup> Day 29, pages 23–24; Excerpts from medical records recovered in respect of Luke

<sup>153</sup> Day 29, pages 24–25; Excerpts from medical records recovered in respect of Luke

<sup>154</sup> Day 29, page 26; Excerpts from medical records recovered in respect of Luke

<sup>155</sup> Day 29, page 26; Amy's Witness Statement

**5.76** When Luke was four years old he sustained a laceration to his forehead, and it bled profusely. Amy took him to the Accident and Emergency Department of Ninewells Hospital. The nurse treating him did not wear gloves so Amy had to divulge that he was HIV-positive, so that the staff would protect themselves. She found this experience distressing. Had the nurse taken the appropriate precautions, she would have been spared having to explain Luke's HIV status.<sup>156</sup>

**5.77** In early 1991, when Luke was five years old, he started taking nightly Co-trimoxazole as prophylaxis against PCP.<sup>157</sup>

**5.78** Amy struggled to cope with the implications of Luke's diagnosis with HIV. She stated that she tried to put his diagnosis behind her, but every hospital visit, which she attended alone with him, was a constant reminder of his condition. She said, '[T]here would be times I would be going up there on my own and I would have [Luke] in my arms ... and I would just be crying on the bus coming home'.<sup>158</sup> 'I was hurting inside, unhappy, bitter and angry at all that has happened'.<sup>159</sup> Amy was referred for counselling in 1987 but, at that time, she was not ready for 'anything like that'.<sup>160</sup> So, in the early days of Luke's diagnosis with HIV, the only support she received was when she spoke to the doctor at his hospital appointments. When Luke was about five years old, Amy became unhappy in her marriage. She did not see the point in carrying on and tried taking her own life 'as I had just had enough .... Looking back I know it was the wrong thing to do but then it was like I had just given up'.<sup>161</sup>

**5.79** In July 1991, Luke was prescribed immunoglobulin. The immunoglobulin was administered to him at the hospital by a drip and each treatment would take about two hours.<sup>162</sup> Initially Luke was prescribed this once a month but in 1996, as he had remained so healthy with a steady CD4 count, it was reduced to once every three months.<sup>163</sup> The doctors advised Amy that they wanted Luke to have this treatment as prophylaxis against bacterial infections. Intravenous immunoglobulin was widely used to treat idiopathic thrombocytopenia purpura (an autoimmune disorder causing a reduction in platelets) in the general population, as well as in those who are HIV-infected. In children there were some positive experiences with using immunoglobulin treatment. Current practice does not include the use of intravenous immunoglobulin in HIV infection, except for severe parvovirus infection (a common infection also known as 'slapped cheek disease') and, rarely, intractable thrombocytopenia.<sup>164</sup> Luke continued to receive infusions of immunoglobulin until 1997.<sup>165</sup>

### *Luke at school*

**5.80** When Luke was five years old he started school. Only the headteacher at the school knew about his infection with HIV. The school had policies and procedures in place which meant that all blood spillages were dealt with in the same way. Luke's headteacher was told about his infection for two reasons: first, to explain why he was often absent from

<sup>156</sup> Day 29, page 27; Excerpts from medical records recovered in respect of Luke

<sup>165</sup> Day 29, page 35; Statement of Clinical Specialist Nurse

school to attend hospital appointments and, secondly, so that she could warn the family if there was an outbreak of chickenpox in the school. Chickenpox can be severe in patients with HIV so any time there was an outbreak of chickenpox at the school, Amy had to take Luke immediately to the hospital. There he was treated with Zoster Immunoglobulin injections, which he received in the top of his legs, and he was prescribed a five-day course of oral Acyclovir (a drug used to treat infections caused by viruses, including chickenpox).<sup>166</sup>

**5.81** Luke enjoyed school and ‘sailed through’ despite his hearing difficulties.<sup>167</sup> When he was seven and a half years old, a specialist nurse joined the local HIV multidisciplinary service as part of a community nursing team. Her remit was to provide information, care and support for HIV-positive patients and their families. She used to arrange Luke’s monthly appointments for his treatment with immunoglobulin. She also saw both of them at his hospital appointments and was always contactable, even outwith normal working hours. She has been, and remains, a good support to both Amy and Luke.<sup>168</sup>

**5.82** During his childhood, Luke suffered from polyps in his nose. Amy described the effects of this as ‘it was always like he was choked up’.<sup>169</sup> He was referred to an Otolaryngologist when he was young for adenoidectomy but, due to his low platelet count, the Otolaryngologist was unwilling to operate. When Luke was older he underwent surgery to cauterise the polyps.<sup>170</sup>

**5.83** In about 1996 Amy and her husband separated. Amy stated that she and her husband ‘drifted apart’.<sup>171</sup> She believes that Luke contracting HIV was a major factor in their separation. Since their separation, Amy and her husband have maintained a good relationship for the sake of their children and the children remain close to their father and his family.

### *Luke’s treatment with antiretroviral medication*

**5.84** In October 1997, Luke’s immunoglobulin treatment was stopped and he was prescribed dual antiretroviral therapy of Zidovudine and Lamivudine. Lamivudine was similar to Zidovudine, in that it was another NRTI.<sup>172</sup> It was introduced as treatment for HIV in about 1995.<sup>173</sup> Luke continued to suffer from enlarged lymph nodes under his arms and in his groin but was otherwise well.<sup>174</sup>

**5.85** In September 1998, when Luke was 13 years old, Dr Tarnow-Mordi and Luke’s parents decided that he should be told that he was HIV-positive. They agreed that it would be better if Dr Tarnow-Mordi explained this to him at the family home.<sup>175</sup> In October 1998, Dr Tarnow-Mordi and the specialist nurse visited Amy, her husband and their sons at home. In his letter to Luke’s GP about this visit, Dr Tarnow-Mordi wrote:

I saw [Luke] recently at home .... We went over the reasons for [Luke’s] regular attendances at the hospital and his frequent medicines and in particular I

<sup>173</sup> Professor Leen’s Report [PEN.012.1044] at 1055

<sup>174</sup> Excerpts from medical records recovered in respect of Luke

<sup>175</sup> Ibid

explained the HIV virus which is inside his white cells and that the drugs he is taking is helping to control this virus and prevent it from damaging his white cells further. We emphasised the need for secrecy about his diagnosis outside the family because people have been and still are sometimes very cruel about this condition because of their own fear of catching it. [Luke] seemed to understand what was said and to accept it very well and his parents seemed satisfied that he had made a good start in understanding his diagnosis. They feel prepared to build on this beginning and answering any question he may have in the future with further assistance from ourselves and yourself whenever appropriate.<sup>176</sup>

**5.86** Amy and the doctors felt the need to emphasise keeping Luke's diagnosis a secret due to the stigma about HIV. Amy has always told Luke that, if the fact he has the virus should become known to others, he should never feel guilty as it was not his fault that he became HIV-positive.<sup>177</sup> It was apparent, as Amy gave her evidence on this matter, that the stigma surrounding the virus and the need to protect her elder son from this has affected her greatly.

#### *Luke's treatment with triple therapy*

**5.87** In November 1998, Luke's viral load showed an increasing level. Dr Tarnow-Mordi decided that it was appropriate to change his treatment from dual therapy to triple therapy, namely Stavudine, Didanosine and Nelfinavir.<sup>178</sup> It was arranged that he start this treatment in the near future. Stavudine and Didanosine are NRTIs. Nelfinavir is a protease inhibitor. Protease inhibitors became available to treat HIV in about 1995, and more generally in 1996, and were usually added to whatever treatment a patient was receiving. The era of Highly Active Antiretroviral Therapy (HAART), involving treatment with up to three drugs, arrived in the second half of the 1990s.<sup>179</sup> Around this time, a new laboratory technique was able to measure the viral load of an HIV patient, and this confirmed the extent of the replication of the viral particles of HIV.<sup>180</sup> The arrival of protease inhibitors heralded a marked improvement in the treatment of HIV. Professor Leen stated that, at the time, some patients were so ill that clinicians thought they would not survive. Some got married in the hospital as they thought they were going to die. They now have children and grandchildren. Professor Leen described it as 'an amazing time' which changed the face of HIV and AIDS completely.<sup>181</sup>

**5.88** In December 1998 Luke contracted a chickenpox-type rash. He was admitted to the hospital for a week's treatment with Acyclovir, and was then discharged home where he took oral Famciclovir (another medication used to treat viral infections, such as chickenpox) for a further seven days. During his admission Luke remained well and his rash resolved uneventfully. While he was an in-patient, Dr Tarnow-Mordi took the opportunity to change Luke's antiretroviral therapy to the new triple regime of Stavudine, Didanosine and Nelfinavir and to increase his dose of Co-trimoxazole. Initially, Luke vomited the Nelfinavir due to its unpleasant taste, but he started taking it with milk which helped. Having told Luke about his HIV status the previous week, Dr Tarnow-Mordi found it helpful to explain to him why he was changing his medication in terms of his underlying

<sup>176</sup> Day 29, pages 40–41; Excerpts from medical records recovered in respect of Luke

<sup>177</sup> Day 29, page 42

<sup>178</sup> Excerpts from medical records recovered in respect of Luke

<sup>179</sup> HAART – Highly Active Anti-Retroviral Treatment. See Chapter 8, *Knowledge of HIV/AIDS Now*, paras 8.43–8.44, where this triple therapy is described

<sup>180</sup> Professor Leen – Day 33, pages 40–41; and his Report [PEN.012.1044] at 1051 and 1052

<sup>181</sup> Professor Leen – Day 33, page 45

virus condition. In his letter to Luke's GP about this admission Dr Tarnow-Mordi wrote 'I don't think he understands the full implications, but he does know that he has HIV and that we are giving him life long drug medicines to keep the virus under control'.<sup>182</sup>

**5.89** Three weeks after starting the triple therapy, Luke's viral load showed a significant reduction, and his CD4 count had increased.<sup>183</sup> In September 2000, his dose of Co-trimoxazole was stopped as there was concern that this was the cause of his low neutrophil count.<sup>184</sup> Luke kept well and continued to attend three-monthly review appointments.<sup>185</sup>

**5.90** Luke left school after fifth year and went to college to complete a one-year computer studies course.<sup>186</sup>

**5.91** In January 2002, Luke attended his first appointment with a new Consultant at the Adults' Infectious Disease Clinic. He was always accompanied to these appointments by one of his parents.<sup>187</sup> Having had such a good relationship with Dr Tarnow-Mordi, Luke's relationship with this new Consultant was not good. Neither he nor Amy liked this new Doctor. They did not like 'his bedside manner'.<sup>188</sup> At this appointment Luke's blood test results were noted to be very encouraging, with a CD4 count of 682 and an undetectable viral load.<sup>189</sup>

### *Luke's non-adherence to his treatment and the subsequent deterioration in his condition*

**5.92** Amy stated that it was always 'a struggle' to encourage Luke to keep taking his medication.<sup>190</sup> She and her husband used to try to encourage and advise him to take his medication but, when he became a teenager, Amy felt that it was his choice and she could only advise him.<sup>191</sup> In the mid-1990s clinicians received frequent complaints from patients about the number of tablets they had to swallow and the large size of them. Nelfinavir was particularly difficult to take.<sup>192</sup> Some tablets could be crushed but this depended on the bioavailability of each type. Others could be dissolved in a liquid, but this would involve extra time and effort, and might not mask the bad taste.

**5.93** In November 2004 Luke stopped taking his antiviral medication. He found the tablets difficult to swallow, did not like the taste of them, and, at one point, told his mother that he did not see the point in taking them.<sup>193</sup> Luke started to miss clinic appointments. He often made up excuses to not attend.<sup>194</sup> In November 2005 Luke attended a clinic appointment accompanied by his father. His CD4 cell count in September 2005 was 323 cells/mm<sup>3</sup> compared to 724 cells/mm<sup>3</sup> measured in August 2004. His viral load in September 2005 was 15,000 copies per ml. 'Viral load' in this context, is a test that measures the amount of HIV virus in the bloodstream. The result is measured in copies (of the virus) per millilitre of blood and it can range from over 1,000,000 copies/ml to fewer than 50 copies/ml. The latter measurement is classed as undetectable. Luke did not appear to be suffering from

<sup>182</sup> Day 29, pages 43–44; Excerpts from medical records recovered in respect of Luke

<sup>191</sup> Ibid, page 50

<sup>192</sup> Professor Leen – Day 33, page 49

<sup>193</sup> Day 29, page 48

<sup>194</sup> Ibid, page 55

any symptoms at that time. He was told that his immune system could deteriorate again to a level requiring antiviral treatment.<sup>195</sup>

**5.94** In June 2006 Amy's younger son developed chickenpox. Luke felt well but in hospital received a seven-day course of Varicella Zoster Immunoglobulin and Valacyclovir (an antiviral drug used to treat infections caused by two common viruses).<sup>196</sup>

**5.95** At a clinic appointment in December 2006, Luke told his Consultant that he was considering restarting his antiviral medication as he had suffered a few infections. At that time he had a mild seborrhoeic dermatitis on his face.<sup>197</sup> In January 2007, Luke's viral load was only 4100 copies/ml, indicating only fairly low replication of the virus. Luke was still keen to restart treatment and so was prescribed Truvada, one tablet daily, and Efavirenz, one tablet daily. Truvada contains a combination of tenofovir and emtricitabine, and both are NRTIs. Efavirenz is an NNRTI.<sup>198</sup> The principal side-effects of these medications were disturbance of renal function, and vivid dreams or even nightmares.<sup>199</sup> Luke had difficulty swallowing these tablets due to their size so he did not take them. In April 2007, the Consultant wrote to Luke advising him that the Truvada tablets could be dissolved in water, but the solution they made had a slightly bitter taste. The Consultant also wrote that he was trying to obtain Efavirenz as a liquid solution.<sup>200</sup> It seems that this did not help Luke, and he did not take these medicines.

**5.96** Between April and June 2007, Luke was prescribed Kaletra (a drug used to treat HIV containing two different protease inhibitors, lopinavir and ritonavir). When Luke attended a clinic appointment with the Consultant on 19 June, Luke told him that he had not taken any of his antiretroviral medication because he could not eat meals on a regular basis and Kaletra was required to be taken on a full stomach.<sup>201</sup> In his letter to Luke's GP about this appointment, the Consultant wrote:

Overall, I was left with the distinct impression that he is seeking excuses for not being on treatment. This is obviously a pointer to non-adherence to prescribed therapy. In such a setting, he can only breed resistance to the drugs and this would leave him in a worse position than no therapy at all.<sup>202</sup>

The Consultant advised Luke to reorganise his meal times.

**5.97** Luke attended for review by the Consultant on 6 November 2007. By this time his CD4 count had dropped to 87 and he remained underweight at 53 kilogrammes. The Consultant wrote, 'things are not going terribly well'.<sup>203</sup> He had a frank discussion with Luke. He wrote:

I have never been fully convinced that [Luke] fully understands the stark choices he faces at present. I pointed out that, in the absence of treatment, HIV could kill him in the relatively near future. However, specific treatments for HIV could prolong his life very significantly and improve his overall wellbeing. I have left him to go away and think about this.<sup>204</sup>

<sup>204</sup> Day 29, page 56; Excerpts from medical records recovered in respect of Luke

**5.98** The Consultant asked Luke's GP to prescribe Co-trimoxazole on a regular basis as a prophylaxis against opportunistic infections. He arranged to review Luke in January 2008 to consider a once daily single pill therapy for HIV.

**5.99** On 23 November 2007, Luke was admitted to Ninewells Hospital with breathing difficulties. He was placed in an oxygenated room and was treated with IV medication. His treatment with Co-trimoxazole was stopped on admission due to him having an adverse reaction to it. Luke was discharged home on 29 November. He was prescribed Dapsone as a prophylaxis against PCP.<sup>205</sup>

**5.100** By January 2008, Luke had gained about 2kgs in weight. Luke reported that he was able to swallow tablets and so the Consultant prescribed him Truvada, one tablet daily and Kaletra, two tablets daily.<sup>206</sup> At the next clinic appointment that February, Luke told the Consultant that he had been unable to swallow any of his antiretroviral medicines. He took a couple of the tablets to the appointment to show the Consultant how big they were. He agreed that they were 'a significant size' but commented that most of his other patients were able to swallow them without difficulty.<sup>207</sup> The Consultant suspected that Luke simply did not wish to take the tablets, and so was coming up with a variety of excuses as to why he was unable to persevere with them. The Consultant agreed to speak to the pharmacist to find out whether the pills could be crushed.

**5.101** After a clinic appointment in May 2008, the Consultant wrote that no further progress had been made. He believed that Luke had come up with a variety of excuses as to why he could not start taking the antiretroviral medication. He considered that they were all part of 'an avoidance strategy' but the underlying problem was that Luke did not wish to take the pills. Obviously, this was the Consultant's understanding of the position. Amy stated that Luke did not discuss these matters with her, and so she was unable to shed light on his thinking about this matter. The poor relationship between this Consultant and Luke will not have assisted, and the Consultant wrote:

I managed to get him to admit that in the absence of treatment he will almost certainly die fairly soon. I explained to him that taking the treatments in a half hearted manner would rapidly breed resistance to the drugs which would never work again. I told him that there was no point in us seeing him again until he is prepared to take the treatments as prescribed. I have left him with an open appointment at the clinic.<sup>208</sup>

**5.102** After this appointment the Consultant wrote to the HIV clinical nurse specialist stating that Luke was continuing to make excuses as to why he could not take his treatment. He stated, 'I think we will all have to take a step back now and let him think it over himself without any prompting or encouragement from ourselves. I suspect we may have had too much intervention and support in the past'.<sup>209</sup> He advised her to wait for Luke to make an approach to them for a clinic appointment.

**5.103** On 7 October 2008, Luke attended an appointment with the Consultant. Luke advised him that he wanted to recommence antiretroviral therapy, and that his mother would help supervise the first couple of weeks of treatment. When the Consultant asked

<sup>209</sup> Excerpts from medical records recovered in respect of Luke

Luke why he wished to restart therapy, Luke apparently stated that he had felt 'a bit poorly' a couple of weeks before.<sup>210</sup> The Consultant undertook to find out if Luke could crush the Truvada tablets before taking them.

**5.104** In November that year, Amy asked the Consultant if Luke could be prescribed some antidepressant medication as he was feeling low. The Consultant referred Luke to a psychiatrist for assessment for a possible depressive illness.<sup>211</sup> In his letter he wrote of Amy's 'great frustration and anger about the transfusion in 1985 and the subsequent stress amongst the entire family'.<sup>212</sup> He wondered about the cause of Luke's reluctance to take treatment. As a result of the referral letter, the local Community Mental Health Services wrote to Luke twice asking him to contact the service to make an appointment. Luke failed to do so and so he had no contact with these services.<sup>213</sup>

**5.105** Due to his failure to take his antiretroviral treatment, Luke's condition deteriorated. On 17 January 2009, he was admitted to Ninewells Hospital with a four-week history of shortness of breath. He had a cough productive of green sputum, and he became breathless on limited effort. A chest x-ray showed lingula shadowing (shadowing of a segment of the left lung). Luke admitted that he was having occasional night-time sweats. He had left-thigh paresthesia (tingling sensations). On examination he was found to be extensively cyanosed (having a bluish colouring due to lack of oxygen) in his nail beds with cold hands. A few crackling sounds were heard in the base of his right lung. An initial diagnosis of PCP pneumonia or atypical pneumonia was made and Luke was started on treatment with Co-trimoxazole at 60% oxygen and IV steroids. Luke was subsequently found not to have PCP and no cause of his chest infection was found. His treatment with Co-trimoxazole was continued and his IV steroids were changed to an oral steroid, Prednisolone. Luke was discharged home on 23 January to continue taking both these medications.<sup>214</sup>

**5.106** During this admission, Luke sent a letter to one of the doctors treating his respiratory problems. It read:

I'm writing to you as regards myself being under [the Consultant]. I feel communication has broken down between us. I feel it hard to open up and express my feelings. I'm starting to have negative thoughts about the outcome of my visit before I've even seen [the Consultant]. I feel a change could do me good.<sup>215</sup>

**5.107** As a result of this letter, Professor Nathwani, a Consultant Physician, started treating Luke in respect of his HIV in place of the previous consultant.<sup>216</sup>

**5.108** In early February 2009, Luke was admitted to hospital again due to a flu-like illness.<sup>217</sup> His symptoms were arthralgia (severe pain in a joint or joints), fevers and feeling 'non-specifically unwell'. During this admission, Luke's liver function tests were noted to be abnormal, but they recovered. He underwent extensive investigations including tests for Cytomegalovirus, Epstein-Barr virus (both part of the herpes family of viruses), adenovirus (a

cause of respiratory illness) and a respiratory tract infection, all of which proved inconclusive. Luke was diagnosed as having a viral infection which resolved without treatment.

### *Luke resumes taking antiretroviral medication*

**5.109** On 11 February, Luke attended a clinic appointment. He was noted to be feeling well and had almost finished his course of Co-trimoxazole. He continued to take Prednisolone. It was planned for him to attend a further clinic two or three weeks later with a view to possibly starting antiretroviral treatment.<sup>218</sup> On 19 March, Luke attended a clinic appointment with Professor Nathwani. At this time Luke had completed his therapeutic course of Co-trimoxazole, but he continued to take one tablet of it daily as prophylaxis against PCP. Luke also started reducing his course of oral Prednisolone with a view to stopping it. Professor Nathwani prescribed Truvada and Nevirapine. Nevirapine is an NNRTI. Luke was prescribed these particular drugs as they were the only antiretrovirals Professor Nathwani could find which could be taken in a liquid preparation.<sup>219</sup>

**5.110** Luke managed to take this medication and has continued to do so. There was a marked improvement in his condition soon after starting the treatment. At a clinic appointment in April, the doctor 'was amazed at how well he [was] looking'.<sup>220</sup> He had gained 9kgs in weight and told her that he was 'feeling really well'.<sup>221</sup> He was noted to be eating well, and Amy's husband reported that he was much more talkative and outgoing. He had finished his course of steroids but continued to take Co-trimoxazole prophylaxis as his CD4 count remained below 200.

**5.111** In July 2009, Luke was suffering from a widespread rash which worsened particularly over his upper anterior chest, back and shins. It was thought to be seborrhoeic dermatitis. Luke was prescribed Itraconazole liquid preparation, Nizoral shampoo and Canesten HC (all antifungal medications).<sup>222</sup> His CD4 count remained low.<sup>223</sup>

**5.112** At a clinic appointment on 8 July 2010, Professor Nathwani thought that Luke was looking the best he had seen him look for a considerable length of time. Once again, Luke had gained weight and was generally feeling very well. He was tolerant of his medication, his last viral load was completely suppressed and his CD4 count was stable at 141. Professor Nathwani noted that there was a family history of cardiovascular disease. HIV treatment, particularly treatment with protease inhibitors, is associated with an increased risk of cardiovascular disease. This risk is increased by about 70% compared to patients in the same age and lifestyle group not receiving treatment.<sup>224</sup> Professor Nathwani asked Luke to pay particular attention to his diet and planned to monitor him from a cardiovascular point of view particularly because of his young age.<sup>225</sup> Professor Nathwani informed Luke that his care was being transferred to a new Consultant in Infectious Diseases.

**5.113** His viral load increased to 160 in September 2010, and his CD4 count was 204 at that time. In November, once again, Luke's rash worsened over his neck, his wrists and his abdomen. It also affected his eyes. The doctor was concerned that this rash was more than seborrhoeic dermatitis. One possibility was that the rash was caused by one of his

<sup>225</sup> Day 29, page 63; Excerpts from medical records recovered in respect of Luke

medications each of which was known to sometimes cause this side-effect. The difficulty was in establishing which medication might be causing it. Luke was prescribed Daktacort cream (a hydrocortisone cream) and was told to continue using the Nizoral shampoo. As his CD4 count had been greater than 200 on two occasions, the doctor thought that it would be safe for Luke to stop taking Co-trimoxazole in the hope that this would improve his rash. He was referred to the dermatologists at the hospital for further advice.<sup>226</sup>

**5.114** When Luke was reviewed in the clinic on 15 December, his skin seemed 'to be a lot improved'.<sup>227</sup> The doctor hoped that this was due to the withdrawal of Co-trimoxazole and diagnosed Luke as being allergic to this drug. In March 2011, Luke's rash looked 'much improved' but flared up when he stopped using the Daktacort cream.<sup>228</sup> Luke's HIV viral load was noted to have fallen below 20 units in December 2010 and his CD4 count had reduced to 195. The new Consultant, Dr Evans, was a little disappointed that the CD4 count was so low. He suspected that the seborrhoeic dermatitis would not completely resolve unless Luke's immune system improved over the next couple of years.

### *The present position*

**5.115** Luke continues to attend clinic appointments every four months. When asked how her elder son is now, Amy said, 'He seems to be doing fine. He has put on weight, he is eating better. I think he appears happier within himself now'.<sup>229</sup> Generally he keeps good health.

**5.116** Luke lives with his brother. He does not work. At one time, when he received benefits, he obtained gardening work through Jobseekers. The work involved carrying heavy loads on his back. Due to his low bodyweight, Luke found this work difficult and was absent for a week. On his return to work, Amy believes that he was picked on by the person in charge and so he stopped work. Luke sometimes looks on the internet for employment, but Amy does not think that he has any plans to find work.<sup>230</sup> She believes that Luke does not want other people to see him taking medication and then ask questions about it. Luke receives a monthly allowance from the Eileen Trust. When asked how Luke spends his time Amy stated:

He doesn't really do a lot at all. He is in the house quite a lot. If he is not with me, he will maybe be with his dad or his granddad but he doesn't go out drinking or pubs or anything like that. And he has never had a girlfriend. He just sort of keeps himself to himself.<sup>231</sup>

**5.117** Amy worries about Luke because he does not have a job and has not been in a relationship. He once told her that he would never be able to have a girlfriend because he has HIV. He is concerned about being in a relationship as he feels that he would have to be open with the person about the fact that he has HIV.<sup>232</sup>

**5.118** Amy stated that she is very bitter and angry about what has happened. She feels that it should not have happened. She stated that she tries to put it behind her but that her elder son's infection with HIV has affected them all. She feels guilty that she moved

out of the family home and left Luke living there with his brother. She would like him to try to become independent, but Luke continues to ask her to accompany him to medical appointments, and when he has to do anything in town. She stated that Luke is very quiet and reserved: 'He is in the house all the time more or less'.<sup>233</sup>

## Frances

**5.119** Frances gave evidence about her father's infection with HIV and Hepatitis C from treatment he received for Haemophilia A. For the purposes of this chapter Frances' father will be referred to as 'James'. James was born in the 1940s. At the time she gave evidence, Frances was 41 years old. She has two younger brothers.<sup>234</sup> Her father died in 1990.

### *James' diagnosis with Haemophilia A and his treatment*

**5.120** James suffered from severe haemophilia, having less than 1% clotting factor. There was no family history of haemophilia and it is thought that his development of the condition was as a result of a genetic mutation. James' mother was told that it was unlikely that James would live to beyond two years of age.<sup>235</sup> James was always treated for his haemophilia at the Royal Infirmary of Edinburgh (RIE). Initially, he was treated with snake venom (a strange but not uncommon treatment for haemophilia in the 1940s and the 1950s), then cryoprecipitate and Factor VIII when these products became available. He needed treatment at least weekly, and often several times a week. James did not have home treatment for his haemophilia until Frances was about nine years old, early treatments having been administered in hospital.<sup>236</sup>

**5.121** Due to his haemophilia, James was unable to attend school. At that time, schools were unwilling to accept children with severe haemophilia. He was home tutored for a while but he received no proper teaching and unsurprisingly he gained no formal qualifications.<sup>237</sup> His lack of schooling deprived James of the opportunity of meeting other children. He had an older sister and there were local children he knew. Despite this, James was a sociable person.<sup>238</sup> He was very active and had a real zest for life. He did not let his haemophilia hold him back.<sup>239</sup> Frances wished her father's occupation to remain confidential. Despite his lack of qualifications, James managed to teach himself a skill and use this to build up his own, successful business.

**5.122** In order to try to avoid having to go into the hospital for treatment, James used to try and treat his bleeds with rest at home. In 1971, James asked his then consultant, Dr Davies, if it would be possible for him to receive prophylactic weekly injections of cryoprecipitate to see if this would mitigate the number of spontaneous bleeds from which he suffered. Dr Davies was willing to try this on an experimental basis with a dose of six packs of cryoprecipitate weekly. In his letter to James' GP about this, Dr Davies stated that James appreciated that there was a small risk of serum hepatitis or even developing an antibody to Factor VIII from the transfusions of blood products, but he thought that this would not be greater than the risk James had, at that time, from the frequent transfusions on admission following bleeds.<sup>240</sup>

<sup>233</sup> Day 29, page 68

<sup>234</sup> Day 30, pages 3–4

<sup>235</sup> Ibid, page 11; Frances' Witness Statement

<sup>236</sup> Day 30, pages 6–7 and page 9; Excerpts from medical records recovered in respect of James

<sup>237</sup> Day 30, pages 4–5

<sup>238</sup> Ibid, pages 7–8

<sup>239</sup> Ibid, page 4

<sup>240</sup> Ibid, pages 8–10; Excerpts from medical records recovered in respect of James

**5.123** By 1975, James was able to self-administer Factor VIII concentrate in the hospital. In a report to a life assurance company, Dr Davies reported that James was in good health except for his haemophilia. He wrote, 'Apart from his haemophilia he is very fit. Nonetheless this disorder constitutes a definite morbidity and mortality risk increase even with modern therapy'.<sup>241</sup> He noted that James had moderate joint deformity from bleeds, mainly of his knees and elbows and less so of other joints. Frances stated that her father's bleeds used to slow him down and they caused him pain. He did not complain of pain but he looked drawn. After he started home treatment, he would inject himself with Factor VIII and then rest. As a result of the frequent bleeds into his joints, James developed arthritis. Frances remembers that he always had slightly bent and swollen joints, especially in his knees and elbows. James received physiotherapy for his joint problems and often wore splints, including at night. He also attended orthopaedic surgeons for treatment and was offered surgical options to treat his left elbow. James was not keen to undergo surgery and so did not pursue that option.<sup>242</sup>

**5.124** Initially, when James started home treatment, in about 1976, he treated bleeds when they occurred. Assisted by his wife, he kept a detailed record of each treatment he took.<sup>243</sup> Frances used to help him make the factor treatment up 'as it took ages to dissolve'.<sup>244</sup> James taught her how to give him an injection and, at the age of 10 years, Frances gave her first IV injection. In 1980, James had prophylactic cryoprecipitate three times a week for three weeks to try to settle a bleed in his left elbow.<sup>245</sup>

**5.125** Frances was unable to say whether James was specifically warned of any risks associated with his treatment for haemophilia but thought that he would have asked about this. She said, 'He was big on being fully informed and wasn't afraid to ask questions. So I expect that he knew whatever risks were known at the time'.<sup>246</sup> It is clear from the medical records that James took an active interest in his therapy. For example, he explored the possibility of prophylactic weekly injections of cryoprecipitate in 1971, and discussed the risk of acquiring 'serum hepatitis' or developing an antibody to the Factor VIII blood products.<sup>247</sup> At this time it is likely that Hepatitis B was the candidate virus.

**5.126** In 1980, Professor Ludlam replaced Dr Davies as the Consultant Haematologist treating James. Frances stated that her father was very happy with the care he received from Professor Ludlam and 'he had a lot of time for [Professor Ludlam]'.<sup>248</sup> In 1982, the family went on holiday to the United States. Professor Ludlam provided James with some Factor VIII to take with him. He advised James to try to avoid the commercial Factor VIII concentrates as 'they may well give you hepatitis'.<sup>249</sup> He suggested that James try to obtain cryoprecipitate for minor bleeds.

### *James' diagnosis with HIV*

**5.127** In about December 1984 Professor Ludlam told James that he had HIV.<sup>250</sup> Subsequent tests on stored samples of James' blood showed that his first positive HIV sample was on

<sup>250</sup> Day 30, page 23

20 June 1984. James had received treatment with 50 bottles of the HIV-infected batch number 0090 of Factor VIII.<sup>251</sup> Having looked at her old diary, Frances remembers that her father told her on 21 December 1984 that he was HIV-positive.<sup>252</sup> She believes that he would have told her 'very soon' after he was informed. Frances was a teenager.<sup>253</sup> At that time, James was running his own business. He had two business premises in Edinburgh and employed staff. Frances' mother did not work. About two weeks before her father told her that he had HIV, Frances heard a news item on the radio about people with haemophilia being affected by HIV in blood products. This meant that the news that her father had HIV did not come as a complete shock to Frances. James was 'quite matter of fact' about his diagnosis with HIV.<sup>254</sup> He told her the result of his HIV test, and what it meant as far as he understood it. He told her that the family would need to be tested for HIV. The risk to them all was low but there was a higher risk to Frances' mother and a risk to Frances as she had helped her father with his haemophilia treatment. He told Frances that he had to avoid blood contact with others. Because of this he moved into the spare bedroom as he used to have frequent nosebleeds. He knew that HIV would shorten his life, but was unsure about the progress of the disease. Frances recorded in her diary that her father told her that he could have five years left. James stressed to Frances that she was not to tell anyone ever about his diagnosis with HIV. He was a very private person.<sup>255</sup> She said, 'The main thing was the stress for secrecy. That seemed to be the only thing that was stressing him out'.<sup>256</sup> The family was subsequently tested for HIV at the haemophilia ward of the RIE and were all negative for the virus.<sup>257</sup>

**5.128** Initially, James only told Frances and her mother about his diagnosis with HIV. Her two younger brothers were not told. Other family members were told later. Frances described this as 'a difficult time emotionally'.<sup>258</sup> Frances' mother was upset. She 'stuck her head down and didn't talk about it at all. My mum ... wasn't much of a talker...'.<sup>259</sup> Like her husband, she was a very private person.<sup>260</sup> Sometime after James' diagnosis with HIV, he and the family were offered counselling by Billie Reynolds, the Haemophilia Sister at the RIE. James refused counselling on behalf of them all. He thought that counselling was 'a waste of time and for people who were weak ...'.<sup>261</sup>

**5.129** Frances stated that, from the time of her father's diagnosis, '[T]here was the beginning of a strange sort of role reversal'.<sup>262</sup> James was very protective of his wife, and there was a shift to the position where he and Frances protected her 'from the harsh reality of life'.<sup>263</sup> Frances used to join her father in his room in the evenings and they would talk. 'He needed someone to speak to and he spoke to me'.<sup>264</sup> She said, 'it was almost like I became my Dad's counsellor, I was the person he spoke to and made plans with. So it changed the dynamic'.<sup>265</sup> Understandably these talks took their toll on Frances. She stated:

<sup>251</sup> Excerpts from medical records recovered in respect of James; James was a member of the 'Edinburgh Cohort' – See Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paras 10.16 onwards

It was very difficult because I couldn't talk to anybody about it. So ... I didn't know how to support him. I didn't know what to do. So I had this overwhelming feeling of responsibility but I didn't know how to meet it ... and I had nobody to ask.<sup>266</sup>

**5.130** Frances' schooling was affected by this too. She had always enjoyed learning but she went from being top of the class at school to struggling academically.

### *James' symptoms of HIV*

**5.131** In about 1986 James became noticeably unwell. He lost weight and his hair thinned. On 7 September 1986 he was admitted to the Royal Infirmary in Glasgow as he had blood in his urine and left-sided ureteric colic (severe pain in the region of the left ureter). He passed some blood clots and the pain settled. He was discharged the following day and attended the Haemophilia Centre at the RIE. He gave a three-week history of feeling generally unwell with malaise and tiredness. He had intermittent sweats but no real drenching night sweats. He had shortness of breath on exertion and while climbing stairs. James continued to suffer from blood in his urine and from left flank pain. On 11 September he was admitted to the RIE for treatment with bed rest, Factor VIII and Pethidine (an opioid painkiller). He recovered with this treatment and was discharged home on 13 September.<sup>267</sup>

**5.132** Three weeks later, on 3 October, James was readmitted to the RIE with recurrence of malaise and night sweats. He was also suffering from nausea, vomiting and intermittent shortness of breath. He looked generally unwell and had a mild temperature. He had palpable cervical and axillary lymphadenopathy (swollen lymph nodes in the armpit). His symptoms settled over 48 hours and he was discharged on 5 October. A provisional diagnosis of AIDS-related complex (ARC) was made.<sup>268</sup>

**5.133** In about December 1986, James was referred to the Wart Clinic at the RIE for treatment of a stubborn wart on the sole of his foot. He received regular treatment with liquid nitrogen and occasionally the wart was pared. He used salicylic acid plasters at home. Despite this treatment, by March 1987 the wart had grown larger and he had developed a new wart on the sole of his foot. The fact that he had haemophilia and was HIV-positive limited the therapeutic options available. The dermatologist treating James asked Professor Ludlam if he had any other suggestion about therapy and whether surgical treatment would be an option.<sup>269</sup> In June 1987 James was discharged from the dermatology clinic, having failed to attend his last two appointments. The doctor noted that when he had last seen James, the warts were improving and he assumed that the warts had resolved.<sup>270</sup>

**5.134** Between the autumn of 1986 and the summer of 1987, James suffered from intermittent bouts of malaise and night sweats. In June and July 1987 he suffered from persistent diarrhoea, night sweats, malaise, some weight loss and shortness of breath on exertion. Between July and October that year he continued to suffer from malaise, night sweats and occasional diarrhoea.<sup>271</sup>

### *James' treatment with Zidovudine*

**5.135** By letter dated 1 October 1987, Professor Ludlam wrote to James advising him that Zidovudine was available as a treatment and that it might be of benefit to him. He asked James to attend an appointment with him on 14 October to discuss this potential treatment.<sup>272</sup> James told Frances about the possibility of treatment. She stated, 'He absolutely wanted to try whatever was going'.<sup>273</sup> At the appointment it was noted that James had had 'longstanding liver enzyme disturbances since 1983'.<sup>274</sup> Non-A non-B Hepatitis and alcohol are noted as being possible causes for this. It was noted that the three indications for James starting treatment were the fact that he had developed ARC, the fact his T4 cell count was progressively declining and HIV antigenemia (the presence of HIV antigen in the blood). On 21 October 1987, James started treatment with Zidovudine, 200 mg every four hours with a double dose at bedtime, presumably so that he could sleep undisturbed for eight hours. During the first week of treatment James experienced a metallic taste in his mouth, but appeared not to suffer from any other side-effects of the medication. James continued to suffer from occasional night sweats and fatigue.

**5.136** At the beginning of June 1988 James suffered from increasing breathlessness on exertion with occasional bouts of breathlessness whilst at rest. He had a dry cough. On 14 June he was seen by a Senior Lecturer in the Department of Respiratory Medicine at the City Hospital, Edinburgh. As well as describing the symptoms of breathlessness, James also told him that he had been suffering from lethargy for six months. James was investigated for pneumonia, particularly PCP, but these tests were negative. He was found to have mild airways obstruction and was prescribed an inhaler of Beta 2 agonist (a drug used to treat asthma). After taking this treatment for a week or so, James was 'slightly better'.<sup>275</sup> Towards the end of June 1988, he developed an upper respiratory tract infection and was prescribed Flucloxacillin for this.<sup>276</sup>

### *James' diagnosis with non-A, non-B Hepatitis*

**5.137** On 28 June 1988 James saw Dr Finlayson, a Consultant Physician at the Gastrointestinal and Liver Service at the RIE, having been referred to him by Professor Ludlam. Dr Finlayson noted that James was mildly jaundiced, his liver was 'very considerably enlarged' and his spleen was palpable. Dr Finlayson considered that James' symptoms were consistent with a diagnosis of chronic liver disease and he thought it was 'probably the consequence of a chronic non-A, non-B Hepatitis virus infection acquired from his blood product therapy'.<sup>277</sup> This was consistent with the state of knowledge about non-A, non-B Hepatitis at the time. He also considered two other possible causes of his liver disease: first, that James was developing AIDS in light of his recent respiratory illnesses and, second, that he was developing a lymphoma in relation to his HIV infection. Dr Finlayson arranged for James to undergo an ultrasound of his abdomen to look at his liver and his spleen and also to see if there were any detectable lymph nodes there. The ultrasound appearances were of diffuse liver disease but no evidence of any enlarged nodes in the upper abdomen. Dr Finlayson then wanted James to undergo a liver biopsy but he was not at all keen on this. He was aware of the risks of a liver biopsy to him, as a

<sup>277</sup> Day 30, pages 44–45; Excerpts from medical records recovered in respect of James

person with haemophilia, and could not understand what the benefits would be. In the event he did not undergo a liver biopsy until the day he died.<sup>278</sup>

**5.138** In July 1988, James developed pain in the left side of his mouth. The floor of his mouth was tender and he had an ulcer of about 0.5 cm in diameter on the surface of his tongue. He was treated with Flucloxacillin and then Penicillin but neither had any effect. He was referred to the Department of Oral Medicine at the Dental Hospital in Edinburgh for advice about treatment.<sup>279</sup> He saw a consultant there. The consultant noted, on examination, that James had 'a major recurrent aphthous ulcer<sup>280</sup> which is one of the more common manifestations associated with HIV infection'.<sup>281</sup> He also noted that James showed signs of early periodontal disease which needed to be treated aggressively from a preventative point of view as it was likely to become an aggressive form of the disease. The doctor arranged for James to have routine oral hygiene care. He prescribed Corsodyl mouthwash for symptomatic relief of his mouth ulcer, which had started to heal.

### *James' treatment with Interferon*

**5.139** Without carrying out a liver biopsy, Dr Finlayson and Professor Ludlam were unable to make a definitive diagnosis of the cause of James' liver disease. They both agreed that a liver biopsy 'would not be without hazard' due to James' severe haemophilia, his prolonged prothrombin time (a measure of the time blood takes to clot) and his propensity to allergic reactions to Factor VIII. Accordingly, they decided to treat him for non-A non-B Hepatitis. In about October 1988, James started a trial of three million units of Interferon treatment, three times a week. Professor Ludlam advised James' GP that it was possible that James might 'be a little upset by the treatment and develop flu-like symptoms'.<sup>282</sup> He planned to reduce the treatment if these side-effects were troublesome. Frances remembers her father taking the Interferon treatment. She said, 'it made him feel quite ill and he had flu-like symptoms. He was very tired and had dreadful diarrhoea'.<sup>283</sup> He continued to work throughout the treatment. Frances stated that her father had a very strong work ethic and 'if he could stand up he went to work'.<sup>284</sup>

**5.140** In about January 1989, James suffered from a bad head cold. He was prescribed Ampicillin (an antibiotic used to treat bacterial infections) for this and the cold resolved. Professor Ludlam saw James in January 1989, and noted that he had made no improvement after the trial of Interferon and so Professor Ludlam stopped this treatment.<sup>285</sup>

### *The deterioration in James' condition*

**5.141** In 1989 James' breathlessness, from which he had suffered since about September of the year before, started to worsen. He remained tired and lost a lot of weight.<sup>286</sup> He was referred to the Department of Respiratory Medicine Clinic at the RIE and underwent a number of investigations there, including a chest x-ray, blood tests and measuring of his transfer factor for carbon dioxide. In May 1989, tests revealed that James was anaemic and this was thought to be the cause of his breathlessness at that time. James was reassured

<sup>285</sup> Ibid, pages 47–48; Excerpts from medical records recovered in respect of James

<sup>286</sup> Excerpts from medical records recovered in respect of James

that he did not have any chronic infection in his lungs, although he was warned that this remained a possibility.<sup>287</sup>

**5.142** Around this time, James also suffered from a sore throat and a cough. He was tired and his cervical glands were swollen. A throat swab was taken and he was prescribed Cephalexin (a drug used to treat bacterial infections). On 2 June 1989 James discussed an impending family holiday with the doctor he saw at a clinic appointment. He told the doctor that he was very keen to go to Spain with his family; he considered that it might be the last holiday he would have with them. He realised that the trip would curtail investigations into his condition and that he might develop other infections or medical problems.<sup>288</sup> The day after this discussion James was admitted to the RIE with a 24-hour history of non-productive cough, increased breathlessness, several episodes of vomiting and a macular rash (a rash characterised by small flat spots). On admission his temperature was 40°C. James underwent a number of investigations. Bronchoscopy confirmed a diagnosis of PCP. He was treated with high doses of intravenous Co-trimoxazole. This was discontinued on 12 June following which James received a week's course of high dose oral Co-trimoxazole. In addition he was transfused with two units of red cells. He underwent a marrow aspirate and trephine (a biopsy of bone marrow sample) which revealed moderately hypocellular (containing fewer than the normal number of cells) marrow. This is a known side-effect of treatment with Zidovudine. James' treatment with Zidovudine was stopped. He was discharged home on 13 June and at that time was prescribed oral Co-trimoxazole, Flucloxacillin, Lactulose (a medication used to treat constipation) and Bisacodyl (a laxative drug). It was planned that James be prescribed a Pentamidine nebuliser as prophylactic treatment for PCP as soon as the equipment for it became available.<sup>289</sup>

**5.143** While he was an in-patient being treated for PCP, Frances' two brothers and her mother left to go on holiday to Spain. James did not disclose to them how seriously unwell he was. A day or two after his discharge he flew out to Spain to join them. Frances remembers driving him to the airport. She did not go on this holiday as she had to sit exams.

**5.144** Frances stated that she was getting on 'badly' in her courses due to her father's illness. During his admission to hospital, James told one of the doctors that Frances was sitting exams at that time. This doctor wrote a letter addressed 'To whom it may concern' at the place where Frances was studying explaining that James was an in-patient in the hospital and that Frances was under external pressure. He asked that, with this in mind, 'a compassionate attitude' be taken to her exam results.<sup>290</sup> Frances also spoke to her tutor about the pressure she was under. She failed the four exams she sat that year.<sup>291</sup>

**5.145** Frances 'really struggled' with her courses.<sup>292</sup> She just managed to pass the exams at the end of first year, but she failed her second year exams twice. She considers that, as a result of her father's illness, she had quite a different student experience to that of her peers, and she did not lead a normal student life. She used to return home a lot. She felt separate from her peers as they seemed to be out having fun, drinking and partying while she felt 'distracted' and was trying to deal with her father's illness.<sup>293</sup>

<sup>291</sup> Day 30, pages 50–51

<sup>292</sup> Ibid, page 51

<sup>293</sup> Ibid, pages 51–52

**5.146** In July 1989 James suffered from abdominal distension, constipation and nausea. He looked anaemic and slightly jaundiced. He developed a small abscess at the site of the bone marrow biopsy procedure. He was prescribed antibiotics for this and it improved. On 23 July, James was given nebulised Pentamidine with no ill effects. His oral Co-trimoxazole was stopped and he continued to receive doses of Pentamidine instead. He continued to suffer from abdominal distension, constipation and tiredness. He developed a further rash. It was suggested that he see Dr Finlayson again, but James was not keen to do so as he did not wish to have a liver biopsy.<sup>294</sup>

**5.147** On 30 August 1989 James met with Billie Reynolds, the Haemophilia Sister. She recorded their discussion in the clinical notes:

Spoke with [James] today. He expressed some wishes regarding his impending demise. He does not want an autopsy, and doesn't wish his wife to be approached on this subject. He is concerned about the writing on the death certificate. Was re-assured about wording on the death certificate.

[Frances] would like a screen placed over the door of the cubicle to ensure privacy when he is very ill.

He has given his consent for us to tell any patient that enquires about him, what is wrong, when he is very ill.<sup>295</sup>

**5.148** James continued to attend the hospital regularly for review as his condition deteriorated. On 3 October he reported that he was 'feeling terrible'.<sup>296</sup> He was tired and sleepy. His abdomen was more distended and uncomfortable. He developed bleeding from his rectum. He asked about re-starting Zidovudine or another 'new American drug'.<sup>297</sup> On 11 October he restarted treatment with Zidovudine. He asked about treatment with Didanosine, but he was told that this was not available. At the end of October James developed itchy skin and eyes; problems which were particularly marked at night.<sup>298</sup> He was referred for a dermatology opinion. The dermatologist considered that the rash was most likely related to his jaundice, or the Zidovudine treatment. She recommended emollient cream.<sup>299</sup>

**5.149** In November 1989 James was admitted to the RIE for review by Dr Finlayson. His main symptoms at this time were hepatomegaly (enlarged liver), jaundice, itch and fatigue.<sup>300</sup> He was diagnosed with cholestatic jaundice (jaundice resulting from inability of bile to flow from the liver to the duodenum). It was suggested that James undergo an ultrasound and CT scan. He was prescribed Questran (a type of medicine called a bile acid sequestrant which works in the intestine where it binds to bile acids).<sup>301</sup> This improved his itch for a while.

**5.150** On 27 January 1990 he was admitted to hospital with a temperature, shortness of breath and coughing. His temperature returned to normal and investigations of his chest were normal. He was discharged home the following day.<sup>302</sup> He continued to suffer

<sup>298</sup> Ibid

<sup>299</sup> Ibid

<sup>300</sup> Ibid

<sup>301</sup> Ibid

<sup>302</sup> Ibid

from intermittent breathlessness.<sup>303</sup> On 6 June James was again admitted to hospital after suffering a reaction to the factor treatment he had received for persistently bleeding gums. While an in-patient, he had a temperature and he was started on broad spectrum antibiotics. He recovered quickly. His treatment with Zidovudine was discontinued and it was planned that he would start treatment with Didanosine.<sup>304</sup> In July, James developed bloating of his abdomen, and there was concern that this was caused by ascitic fluid (fluid which accumulated in the abdominal cavity).<sup>305</sup>

**5.151** Some weeks after this, James woke one morning suffering from a bleed in his abdomen. He said to Frances' mother 'this is it'.<sup>306</sup> He was admitted to hospital that day. He underwent a laparotomy<sup>307</sup> at which the possibility of bleeding from his spleen was raised. A splenectomy was performed but no other source for the bleeding was identified. After this procedure he remained hypotensive (with low blood pressure) and it became clear that the intra-abdominal bleeding was continuing. He was treated with 20 units of blood, fresh frozen plasma, platelets, Factor VIII, antibiotics, adrenaline and dopamine. Sadly, the bleeding persisted and James died later that night.<sup>308</sup>

**5.152** On the day James died, a Friday, Frances was preparing to sit exams on the following Monday. This was her 'last shot' at the exams. Having failed the exams a number of times before, she had been expelled. She successfully appealed her expulsion and was given one last chance to pass the exams.<sup>309</sup> James was aware of this and was keen that Frances sit her exams. When he developed abdominal bleeding he asked his wife not to tell Frances. However, Frances' brother telephoned her and Frances was able to reach the hospital before her father died. When she arrived her father was on a ventilator. Frances' mother asked her 'How will I know when he's gone?' and Frances said that she would tell her. Frances arranged his funeral.<sup>310</sup>

**5.153** James' request for AIDS not being recorded on his death certificate was adhered to and no autopsy was undertaken. His death was reported to the Procurator Fiscal's office due to the fact that he was HIV-positive.<sup>311</sup> A liver biopsy taken at the time of the splenectomy revealed that he had established cirrhosis.<sup>312</sup> A retrospective test carried out on 13 January 1992 on a blood sample dated 5 January 1988 confirmed that James was positive for the antibody to the Hepatitis C virus.<sup>313</sup>

### *Specific impacts of James' infection with HIV*

**5.154** Frances stated that finding out he had HIV had 'a massive impact' on her father.<sup>314</sup> She stated that, when he was younger, her father knew he would not live a long life as a result of his haemophilia, but his life expectations changed when treatment with cryoprecipitate and factor concentrate became available.<sup>315</sup> Knowing that he had HIV curtailed his greatest hobby (which Frances wishes to remain confidential). It also had

<sup>303</sup> Ibid

<sup>304</sup> Ibid. Didanosine was approved in 1991, but was available on a named patient basis in 1990

<sup>314</sup> Frances' Witness Statement

<sup>315</sup> Ibid

'a huge impact' on his relationship with his wife.<sup>316</sup> Frances stated that her father was a very tactile man and not being able to share a bed with his wife would have been 'a real trauma' for him.<sup>317</sup> It also took his focus away from his children, and he was unable to father them as well as he had done before his diagnosis with HIV.

**5.155** James was a successful businessman and was fairly comfortably off. As he had to reduce work due to his illness, there was less income for the family. When he died his business was still operational. After he was diagnosed with HIV, James took out some life assurance. He managed to find some policies which did not exclude paying out even if the death was attributable to HIV. On his death, the MacFarlane Trust made a payment of £60,000 to the family. This money, together with the rental from the shops which James had owned, and the 'money from insurance' supported Frances' mother and Frances' younger brother.<sup>318</sup> James had arranged everything for his wife. After his death, Frances' mother did not know how to pay the gas bill.

**5.156** Frances' mother was devastated by her husband's death, she 'fell apart'.<sup>319</sup> She had 'totally devoted herself to [James]. Her family and her husband were her whole life'.<sup>320</sup> After James was diagnosed with HIV, both her father and mother started drinking. After his death, Frances' mother continued drinking and she eventually became an alcoholic. She also increased her smoking habit from about 20 cigarettes a day to 60. Latterly she drank coffee and vodka and did not eat. In 2000 she died weighing just five stone.<sup>321</sup> Frances was 30 years old when her mother died. At this time her younger brother was in higher education so Frances and her other brother supported him through this.<sup>322</sup>

**5.157** The elder of Frances' two brothers was not told about his father's illness until a few months before his father died, when he was 18 years old. Up until this time, her father's illness had been downplayed. The family was used to him going to the hospital. The elder of the two brothers was unaware how unwell his father was. Frances remembers persuading her father to tell this brother about his infection because she believed that it was important that he have some warning about his father's condition. After the elder brother was told about his father's illness, he had only a short period of time to come to terms with this before his father died. He became very angry.<sup>323</sup> Frances believes that this brother was a little resentful of her as she knew more about her father's illness than he did. After her father died, he felt that he needed to be the man of the family but did not know how to be that man. Frances stated that he is similar to his parents in that 'he is not a talker, so we never really discussed how it affected him because he doesn't want to talk about it; but his life became smaller'.<sup>324</sup> Frances' brother had a road traffic accident which affected his ability to continue working in his job. Frances believes that it is likely that he is fit for other types of work but he has not worked since the accident. Frances believes that he is 'emotionally damaged. It's too big a thing to retrain. Whereas if my dad had been around, he would have had more of a push, more support'.<sup>325</sup>

<sup>323</sup> Day 30, page 57

<sup>324</sup> Ibid, page 58

<sup>325</sup> Ibid, pages 58–59

**5.158** The younger of Frances' two brothers provided the Inquiry with a statement. He recalled, when he was five years old, being taken to the blood transfusion centre for a blood test. He did not know why. When he was 18 or 19 years old he discussed the blood test with his mother and was shocked to learn that the blood test was to determine if he had been infected with HIV. He remembered that his father was often in hospital but he did not know the reason for this. His parents slept in separate beds for as long as he could remember. He thought that this was normal because he slept in a separate bedroom from Frances. He stated that once when a friend came to the house, he showed him around. His friend was amazed when he saw that his parents slept in separate beds.<sup>326</sup>

**5.159** He stated that his father could be an angry, irritable man who, occasionally, was very mean to him. When he was about seven years old, his father threatened to throw out all his toys as he had not tidied his bedroom in the allocated time. He thought that his mother was the voice of reason.<sup>327</sup>

**5.160** He was 10 years old when his father died. Frances was away continuing her studies and his older brother seemed 'a very angry person' at this time.<sup>328</sup> The older brother remained at home until he attended higher education about two years later. Frances' youngest brother considered that all his father's friends disappeared after his father died. He felt angry with them for not supporting his mother. When he was older he learned that some of the friends had tried to support her. They had tried to introduce her to other men but she was not interested. After his father died, he stated that he did all the gardening and as he got older he did more of the housework.<sup>329</sup>

**5.161** When he was 16 years old, his mother said to him that she was proud that she had seen all her children grow up, and that she could die now. By that time, she had no appetite and was very frail. He did not recall her drinking excessively during his school days. When he returned home from school she was always interested in his day, and was not drunk. She smoked a lot. By the time he was 18 years old, his mother was drinking more. She would get up during the night and fall over. He got up then to help her back to bed. When he was 20 years old, his mother fell during the night and broke her hip. She was admitted to hospital where she died three weeks later from liver failure.<sup>330</sup>

**5.162** After her father's death, Frances did better academically and obtained a professional qualification. She has become prone to anxiety and depression. Her father's infection with HIV and her mother's subsequent problems have played a significant role in her development of these symptoms. In April 1997 Frances attended her GP with stress, low mood and anxiety symptoms. Frances believes that this was a delayed reaction to the stress she was under as a result of her father's illness. Frances was initially prescribed Fluoxetine (an antidepressant medication). This was changed to Paroxetine (another antidepressant medication) in August 1997, and she continued to take this until the following December. In January 1998 she again attended her GP with recurrent low mood and anxiety. This did not improve by February and so, once again, she was prescribed Paroxetine. Initially Frances responded well to this, but she became of low mood and anxious again in late 1998. In January 1999 her dose of Paroxetine was increased. She was signed off work

<sup>330</sup> Day 30, page 61; Statement of Frances' youngest brother

from February until September 1999. She attended a psychiatrist for treatment, and he prescribed her with Venlafaxine (a different antidepressant medication) with good effect. She continued to take Venlafaxine until October 2001.<sup>331</sup>

**5.163** Frances' GP provided the Inquiry with a brief medical report. In it she stated:

Over the years Frances has demonstrated a very resourceful personality, coping incredibly well ... as well as dealing with her family issues. I have no doubt that her father's illness and in turn the effects that this had on her family have had an immense role to play in [these problems].<sup>332</sup>

**5.164** Frances stated that it is hard for her to imagine what her life would have been like had her father not been infected with HIV. She believes that, had she had some support at the time 'it possibly wouldn't have had quite such an ongoing effect'.<sup>333</sup> She stated:

I think one of the difficult things is a sense of shame ... and I know there is not real shame but they are not neat, tidy acceptable deaths. It subsequently means that I don't feel able to talk about them. My dad had AIDS and my mum was an alcoholic. It's not, you know, 'My dad had a heart attack'. It has contributed to quite a private personality. This is – this has been quite a difficult process for me because I'm talking about things that I don't talk about. And I have done the work, you know, I have had some counselling myself, I don't share my parents' views on counselling.

I have done the work and I have dealt with it, but it's just utterly changed my life. It has affected how I relate to people. It has no doubt affected my choice of [work], it has affected my relationships. It has influenced my choices in – whether or not to have a family. I don't have children. It was just too difficult to think about, because my dad is a haemophiliac, I'm a carrier. It was too difficult to think about having a child but it was bad enough going through it with my dad. With the possibility of going through it with a son was just too hard. That makes me sad.<sup>334</sup>

## David

**5.165** At the time he gave evidence to the Inquiry, David was 44 years old. He is married and has a daughter. David was unemployed when he gave evidence, and he wished his previous occupation to remain confidential. David has Haemophilia B. He acquired both HIV and Hepatitis C from his treatment with blood products.<sup>335</sup>

### *David's diagnosis with Haemophilia B and his treatment*

**5.166** David was diagnosed with Haemophilia B when he was three years old. He has a family history of haemophilia. Five of his cousins have Haemophilia B. His clotting factor is about 13% of normal, and his haemophilia is classified as moderate.<sup>336</sup>

---

<sup>331</sup> Day 30, page 62; Statement of Frances' GP

<sup>332</sup> Day 30, pages 62–63; Statement of Frances' GP

<sup>333</sup> Day 30, page 63

<sup>334</sup> Ibid, pages 63–64

<sup>335</sup> Ibid, pages 80–81

<sup>336</sup> Ibid, pages 81–82

**5.167** As a child David was treated at Yorkhill Hospital in Glasgow, and this is where, in October 1970, when he was four years old, he received his first treatment with blood products. After a fall, he sustained bruising of his face and a bleed in his left knee. He was treated with a rapid intravenous injection of fresh frozen plasma.<sup>337</sup>

**5.168** David only needed treatment for his haemophilia if he had an accident, or received dental treatment. He estimated that he had such treatment about once a year. As a child his treatment for bleeds usually involved an admission to hospital for about a week. In addition to treatment with blood products, he was also treated with physiotherapy, splints and bed rest. He often used a wheelchair while he was in hospital.<sup>338</sup>

**5.169** David recalled that, in about 1977, treatment for his haemophilia became easier. This is likely to have been when he started treatment, in hospital, with Factor IX concentrate. It reduced the time taken to receive treatment, and it seemed to be effective more quickly. As a result he spent less time in hospital.<sup>339</sup>

**5.170** David was aware that it was not normal to need treatment after a fall so he came to understand that he was different from his friends. At school he was wary of contact sports. He would have liked to play rugby but was unable to do so. Instead he played football and sometimes sustained injuries as a result. In 1979, when David was 13 years old, he sustained a bump to his right knee while playing football. He was treated with bed rest, Factor IX, a splint, a cast and then a walking support. He missed about three months of school due to this injury. His school was very supportive of him. When he was discharged from hospital some of the teachers came to his home and taught him there. They sent him homework. David believes that his haemophilia did not have a detrimental affect on his schoolwork, or the qualifications he obtained at school.<sup>340</sup>

**5.171** In 1981, when David was about 15 years old, his haemophilia care was transferred from Yorkhill Hospital to the Glasgow Royal Infirmary (GRI), under the care of Professor Forbes.<sup>341</sup> In 1982, when David was 16 years old, he started to administer Factor IX concentrate at home. At that time David had marked synovitis (inflammation of the synovial membrane) of both knees. He was instructed to give himself two vials of Factor IX concentrate weekly. He was also told to take Factor IX concentrate at the first sign of a bleed. David had a good response to the regular treatment with Factor IX and the pain and stiffness in his knees improved. In 1983 blood tests showed that David had raised serum transaminases (enzymes in the blood). Professor Lowe, a Senior Registrar at the time, noted that such results were commonly found in people with haemophilia who were on regular treatment. In keeping with the clinicians' state of knowledge at the time, it appears that non-A non-B Hepatitis was considered as a cause for this. David has no recollection of these blood test results being mentioned to him.<sup>342</sup> In 1984, during routine screening for Hepatitis A, David was warned of the risk of infection with this virus from his treatment. He was not warned of the risk of being infected with any other virus as a result of his haemophilia treatment.<sup>343</sup>

<sup>342</sup> Day 30, page 94; Excerpts from medical records recovered in respect of David

<sup>343</sup> Day 30, pages 102–103

**5.172** On 25 January 1985 David attended a clinic appointment at the GRI.<sup>344</sup> As usual he gave a blood sample. This was tested for HIV and was reported on 28 January to be negative. David told the Inquiry that at that time he was unaware that he was being tested for HIV, although he did understand that various tests were undertaken as part of routine screening at clinic appointments. David continued to take prophylactic Factor IX until about July or August 1985. By then David's knee problems had settled. He kept a record of each treatment he gave himself. This record detailed the date he administered the treatment, and the serial numbers of the bottles of factor concentrate that he used. David handed these records into the hospital at the time of further treatment.<sup>345</sup>

### *David's diagnosis with HIV*

**5.173** On 8 November 1985, David attended one of his routine haemophilia clinic appointments. At this time, David was 19 years old and he was working. He has worked in the same industry throughout his working life. The notes of this appointment record that David was feeling well. They also record that he was HIV-negative as at 25 January 1985 and that he was given a Haemophilia Society booklet.<sup>346</sup> David had no recollection of being told that a test had been negative for HIV. He gave a blood sample at this appointment which was tested on 12 November and found to be HIV-positive.<sup>347</sup> When David gave blood samples at his clinic appointments, he understood that these samples were being tested to monitor his haemophilia and to check for Hepatitis A and Hepatitis B. He did not know that his blood sample would be tested for HIV.<sup>348</sup>

**5.174** About a week after the appointment on 8 November 1985 David received a telephone call from the Haemophilia Department asking him to come in to the hospital to meet with Professor Lowe. He was not given any explanation for this. Having just attended a clinic appointment, David was unsure of the purpose of the meeting. He had heard of HIV from articles in the press. He was worried about it as he knew of the risk of transmission of the virus by blood products but, as stated above, he did not know that he had been tested for it.<sup>349</sup>

**5.175** On 2 December, David attended the arranged appointment with Professor Lowe. David was alone when he went to this appointment. He felt that, while having someone to 'lean on' would have been helpful, it would not have changed the fact of his infection.<sup>350</sup> Professor Lowe explained to David that he had been infected with HIV from blood products, and that he was now HIV-positive. David formed the impression that Professor Lowe was not 'entirely comfortable' speaking one-to-one with him about this and it felt to David as if Professor Lowe wished to convey the news to him and then move on. He thought that Professor Lowe spoke to him in a very matter of fact way.<sup>351</sup> Professor Lowe told David that the doctors did not know much about the virus, and gave David some leaflets about general wellbeing and what was known about the virus at the time. He warned him of the risks of secondary infection. He told him about the dangers of cuts, blood spills and unprotected sex. David was told that his girlfriend would need to be tested for HIV. Professor Lowe told him

<sup>347</sup> Excerpts from medical records recovered in respect of David

<sup>348</sup> David's witness statement

<sup>349</sup> Day 30, pages 103–104 and 106

<sup>350</sup> Ibid, page 114

<sup>351</sup> David's witness statement. The manner in which David was told of his diagnosis with HIV, including Professor Lowe's comments on this, is discussed in more detail in Chapter 33, *An Investigation into the Systems in Place for Informing the Patients about the Risks – HIV/AIDS*, para 33.325

to lead a healthy lifestyle. He told David that he would continue to monitor his condition by the usual routine checks and that they would give him further information about the virus as it became available. As David recalled, apart from this general information, no advice, counselling or support was offered then or subsequently.<sup>352</sup> The notes of this appointment suggest that David was also told that he had non-A non-B Hepatitis, although he does not remember being told that at the time.<sup>353</sup>

**5.176** It was put to David in oral evidence, that Professor Lowe's position in response to David's characterisation of his manner, was that telling him about his infection was very difficult, because of the uncertainty about the virus and its prognosis, and that he, Professor Lowe, had tried his best.<sup>354</sup> David made no significant comment.<sup>355</sup> It was also suggested that he had been offered counselling, after his diagnosis, from Dr Wilkie and/or Miriam Guthrie, a social worker at the GRI. David said that he was aware that there was a social worker, but that he had never spoken to her.<sup>356</sup>

**5.177** David felt numb immediately after being told that he was infected with HIV. He stated that he then felt a number of emotions. He thought, 'Well, what does this mean and what does the future look like or lack of it?'<sup>357</sup> From what he had read in the newspapers, he thought that the prognosis for him was a life expectancy of eight to 10 years.<sup>358</sup> David also felt angry that he had been tested for the virus without his knowledge, and without his consent.<sup>359</sup> Questions of practice, in 1985, in relation to the testing of blood samples without a patient's consent are discussed in detail in Chapters 33 and 34. David was still living with his parents and after this appointment he returned home and told them about his diagnosis. They were shocked, and wanted to speak to someone at the hospital to understand the implications of this diagnosis for David. On 4 December, David and his mother saw Professor Lowe at the hospital. David's recollection is that their discussion then was very similar to the discussion he had had with Professor Lowe two days before.<sup>360</sup> David's girlfriend was tested for HIV. She and David attended an appointment with Professor Lowe later in December. She was advised that the result of the test was negative, but that she should undergo repeat tests.<sup>361</sup>

**5.178** Following the appointment on 2 December, Professor Lowe advised David's GP that if David needed any blood tests, they should be carried out by the Haemophilia Unit at the GRI. He also arranged for David's dental care to be transferred from his normal dentist to the hospital dentist, so that all appropriate precautions could be taken.<sup>362</sup>

**5.179** After his diagnosis with HIV David felt 'huge uncertainty'.<sup>363</sup> He stated:

[A]t that point it was a case of almost living from day-to-day, every indication at that point was you could expect a life expectancy of eight to ten years and each time you attend the unit, you are wondering 'What are my results going to be now? Is it getting any better? Is it worse? Is it stable?' You just don't know.

<sup>363</sup> Day 30, page 119

So there was always the anxiety and a general feeling of anxiety, just simply because you had no idea what the future would be like, and I guess being guarded as well in your relationships with people.<sup>364</sup>

**5.180** Due to the ‘huge stigma’ surrounding HIV, David did not tell anyone other than his parents and his girlfriend about diagnosis with it. He did not tell his brother, sister or any of his friends.<sup>365</sup> His siblings still do not know that he is HIV-positive.<sup>366</sup>

### *David’s symptoms of HIV*

**5.181** At the time David was diagnosed with the virus in December 1985, he had some ‘small enlarged lymph nodes in the neck and somewhat larger lymph nodes in both [armpits]’.<sup>367</sup> He carried on attending three-monthly clinic appointments at the Haemophilia Unit. He often saw a junior doctor and gave blood samples. He assumed that the doctors monitored his HIV status, but this was not discussed with him.<sup>368</sup> In June 1986 David had a palpable lymph node on the left submandibular region (situated under the jaw bone), but was otherwise well.<sup>369</sup> In April 1987 he had swollen lymph nodes in the left supraclavicular (neck) and right axillary (armpit) regions.<sup>370</sup> In February 1988 he had no swollen lymph nodes.<sup>371</sup>

**5.182** In November 1988, David was admitted to the GRI due to bleeding gums. He was treated with IV antibiotics and made excellent progress. A swab of his gums was taken and showed evidence of a heavy mixed growth of mouth flora. The report of the sample noted that the significance of the result was doubtful as little was known about the microbiology of dental plaque in HIV-positive individuals.<sup>372</sup>

**5.183** Additionally, in 1988, David developed sinusitis and persistent warts on his hands. He had swollen lymph nodes under his armpits. His CD4 count remained normal. Liver function tests showed continued elevation in transaminases. In August 1989 David’s general health was good. He had no swollen lymph nodes. He suffered from bleeding gums and once again this was thought to be due to a bacterial infection. He was treated with IV antibiotics followed by oral antibiotics.<sup>373</sup> At a review appointment in March 1990, David was found to have developed swelling of lymph nodes in both armpits. His serum transaminases remained raised.<sup>374</sup>

**5.184** David was encouraged to attend his three-monthly clinic appointments. It was quite a challenge for him to do so as his employers were unaware of his condition. The hospital was 10 miles from his place of work. He stated that he was always vague with his employers about why he needed to go to the hospital. Also, he tried to fit his clinic appointments around a time when he would be on annual leave, or when there was an easy way to attend the hospital without having to explain why he was absent from work.<sup>375</sup>

<sup>374</sup> Excerpts from medical records recovered in respect of David

<sup>375</sup> Day 30, page 124

**5.185** In May 1990, David had persistent soft enlargement of his cervical and axillary lymph nodes which meant that he fell into the category of persistent generalised lymphadenopathy as regards his HIV infection. His CD4 count had fallen slightly to 429 cells/mm<sup>3</sup>; this was at the lower end of the normal range. He continued to have elevated serum transaminases. Professor Lowe mentioned the possibility of treatment with Zidovudine. As he felt well, David was resistant to the idea of treatment.<sup>376</sup>

**5.186** In July 1990 David got married. Before their wedding David told Professor Lowe that he and his fiancée had a full discussion about the risk of transmission of HIV infection. They used condoms and took precautions with blood. Professor Lowe offered David's fiancée the opportunity to meet with the Haemophilia Unit social worker, or a consultant gynaecologist, but David's fiancée declined this.<sup>377</sup> Professor Lowe also gave David advice about holiday insurance for his honeymoon.<sup>378</sup> David was aware that if he declared that he was HIV-positive he would be declined cover and so he did not declare this and bought travel insurance to cover other risks.<sup>379</sup>

**5.187** David remained well. In October that year the possibility of treatment with Pentamidine (a medication given to prevent PCP) and Zidovudine was raised with David. He remained reluctant to have treatment unless it was necessary.<sup>380</sup>

#### *David's diagnosis with Hepatitis C*

**5.188** In April 1991 David tested positive for the antibody to the Hepatitis C virus.<sup>381</sup> Around this time Professor Lowe informed him that he had been infected with Hepatitis C from blood products.<sup>382</sup> David stated,

It felt exactly the same as when he told me I had got HIV. He was very matter of fact about it. He did not tell me much about the severity of the virus, the health implications of it or the risk of secondary infection. He told me that they would continue to monitor my liver function tests at my routine haemophilia clinic appointments.<sup>383</sup>

**5.189** Between 1991 and 1997 David's CD4 count fluctuated between about 270 cells/mm<sup>3</sup> and 370 cells/mm<sup>3</sup>.<sup>384</sup> Other than swollen lymph nodes, David remained asymptomatic in respect of both HIV and Hepatitis C. He continued to attend the GRI for monitoring of his condition. In November 1995 the responsibility for the HIV monitoring and managing of haemophilia patients at the GRI was transferred to a consultant specialising in infectious diseases.<sup>385</sup> Towards the end of 1997 David developed a facial rash. He was prescribed Tetracycline (an antibiotic cream) for this.<sup>386</sup> In May 1999, David's CD4 count was noted to have shown a very slow decline. The doctor considered that he was at risk of opportunistic infections and so prescribed him Co-trimoxazole indefinitely. David was warned of a 5–10% risk of hypersensitivity reaction to this medication. His viral load of HIV was also

<sup>386</sup> Excerpts from medical records recovered in respect of David

noted to have increased 'modestly', but David remained reluctant to start antiretroviral therapy.<sup>387</sup>

**5.190** David was aware that once he started taking the treatment he would have to continue to do so, and it would then become part of his daily life. He felt that once he started taking medication he would be 'on a downward spiral'.<sup>388</sup> Instead, David did what he could to stay healthy. He took exercise, watched his diet, did not smoke and did not drink to any great extent.<sup>389</sup>

### *Family planning advice*

**5.191** In 1992, Professor Lowe referred David and his wife to a Senior Lecturer in Women's Reproductive Health at the Glasgow Royal Maternity Hospital to discuss the possibility of having a family.<sup>390</sup> David and his wife wanted to obtain more information about the options available to them at that time. David stated, 'We wanted to have a family as naturally as possible and really risk-free'.<sup>391</sup> David was unwilling to put his wife at any risk of acquiring HIV.<sup>392</sup> Having had an initial discussion with the doctor about their options, they were re-referred to her in October 1994.<sup>393</sup> David found seeing the doctor very helpful. She told him a lot about HIV with regard to looking after himself, the precautions he should take, the health implications of the virus and the risk of secondary infection.<sup>394</sup> In 1996 the doctor contacted a colleague in London to explore the possibility of sperm washing, followed by artificial insemination. She was told that, at that time, the service was not yet available in the UK and that the limited tests of the procedure in Italy had not provided proof that there was no risk of infection to the woman.<sup>395</sup> Having considered the options open to them, David and his wife decided that the best option was donor insemination. They attended the Assisted Conception Service at the GRI and their daughter was born as a result of this procedure.<sup>396</sup>

**5.192** Over the years and due to his fluctuating CD4 count and viral load, there were frequent discussions about treatment. In 2000, David was found to have Genotype 3 of Hepatitis C which was known to be 'relatively favourable' to treatment with Pegylated Interferon.<sup>397</sup> David was given some written information about Pegylated Interferon and asked to consider it.

**5.193** In April 2001, David and his wife were again referred to the doctor at the Glasgow Royal Maternity Hospital for advice about having a second child. They were interested in discussing the possibility of sperm washing and artificial insemination. By this time Dr Seaton, an Infectious Disease Consultant had taken over from the previous consultant. Dr Seaton was planning to treat David with Pegylated Interferon and Ribavirin. David was told that conception was contraindicated while taking this treatment, because of the unknown risks of congenital abnormalities.<sup>398</sup>

<sup>398</sup> Excerpts from medical records recovered in respect of David

*David's treatment for HIV*

**5.194** In July 2002, David's CD4 count 'dropped substantially' to 198 cells/mm<sup>3</sup>.<sup>399</sup> Dr Seaton noted that David had 'a lot of minor symptoms' but, other than a facial rash, David could not remember what these symptoms were.<sup>400</sup> As a result of this change in David's condition, Dr Seaton decided that treatment for HIV was more appropriate than treatment for Hepatitis C and he discussed this with David and his wife. In August 2002 David's CD4 count had risen to 319 cells/mm<sup>3</sup>. He had seborrhoeic dermatitis. Dr Seaton remained concerned that, despite this increase in David's CD4 count, starting treatment for Hepatitis C would lead to further drops in his CD4 count. David and his wife agreed that he should start treatment for HIV on their return from holiday at the end of September 2002. David was prescribed Daktacort (hydrocortisone) cream for the dermatitis.<sup>401</sup>

**5.195** In the following September David started treatment for HIV with Efavirenz (an NNRTI), and Combivir (a combination of Zidovudine and Lamivudine, both NNRTIs). David took the Efavirenz at night time and the Combivir twice a day, one tablet in the morning and one at night time. David tolerated the treatment very well. Initially, he noticed some vivid dreams as a result of Efavirenz. He also experienced some episodes of dizziness if he got out of bed during the night.<sup>402</sup>

**5.196** In January 2003 David's viral load of HIV had dropped to below 50 copies/ml, compared to 77,000 copies/ml in October 2002.<sup>403</sup> His CD4 count was 392 cells/mm<sup>3</sup>. He continued to tolerate the treatment well. He asked to defer starting treatment for Hepatitis C for a further three to six months. In October, despite excellent compliance with the medication, David's viral load increased briefly to 330 copies/ml. It then returned to below 50 copies/ml.

*David's treatment for Hepatitis C*

**5.197** In January 2004 David started treatment for Hepatitis C. He was prescribed Pegylated Interferon and Ribavirin which he took in addition to the Efavirenz and Combivir. David found the side-effects of the treatment for Hepatitis C 'draining'.<sup>404</sup> In March 2004, Dr Seaton noted that David was suffering 'substantial symptoms' from the treatment. He suffered flu-like symptoms over the weekend, having taken the injection of Interferon on the Friday of each week. He deliberately took the injection on a Friday so that he could recover over the weekend and be able to work the following Monday. In the first six weeks of treatment his haemoglobin dropped by four grams; a very significant drop. He attended the ward each week for treatment with an injection of Erythropoietin (a hormone that controls red blood cell production).<sup>405</sup> David suffered from exhaustion, depression, nausea, loss of appetite, weight loss and fatigue. He felt like he had flu for a year. To his credit, David managed to keep working for the first eight months of this treatment, but had to stop during the last four months of his treatment due to the side-effects. In January 2005, David's GP wrote that he was full of admiration for David having persevered at work for as long as he had. David stated that the treatment is 'not something I ever wish to have to repeat'.<sup>406</sup> While taking this treatment, David was concerned about the effect it would

<sup>406</sup> Day 30, page 144

have on the HIV virus. As the treatment affected him so badly, he thought that it could well be affecting the HIV virus. In fact, David sustained a good CD4 count throughout the treatment.<sup>407</sup>

**5.198** Two months after starting treatment with Pegylated Interferon and Ribavirin, David's liver function test results started to improve. This improvement encouraged David to keep taking the treatment despite the side-effects. When he finished this treatment he was told that the Hepatitis C virus was undetectable. David was told that if the virus remained undetectable for two years, he would be deemed to be cured of the Hepatitis C virus. He spent the next two years hoping that this would be the case. Two years after completing his treatment with Pegylated Interferon and Ribavirin, David remained Hepatitis C PCR negative and he was told that he was cured of the virus.<sup>408</sup>

**5.199** In October 2008 David's antiretroviral therapy was changed from Combivir to Kivexa (a combination of Abacavir and Lamivudine). This change was to reduce the risk of therapy-related lipodystrophy (fat loss, often from the face) which had been found to be associated with Zidovudine.<sup>409</sup>

**5.200** David had continued to attend regularly at his HIV clinic appointments. He has remained relatively asymptomatic, and has tolerated his antiretroviral treatment to date.<sup>410</sup>

### *Specific impacts of David's infection with HIV and Hepatitis C*

**5.201** David stated that his infection with HIV has 'hugely' impacted on his family life. He and his wife were unable to conceive children naturally. David's daughter is not yet aware of how she was conceived. This is something David and his wife will have to speak to her about when she has the maturity to understand it. Understandably, David is concerned about the impact this will have on his daughter and how she will react to this. David has asked the hospital, and the MacFarlane Trust, for advice on how and when to explain this to a child but he has been advised that there is no specific information tailored for children.<sup>411</sup>

**5.202** David and his wife's attempts to have a second child failed. David's wife suffered a number of ectopic pregnancies and a miscarriage. They were advised by a doctor at the Assisted Conception Service that assisted conception itself increases the likelihood of ectopic pregnancies. Had David and his wife been able to follow the natural course of having a family, they would have done so, and hopefully they would have had more children. His wife might not have suffered these failed pregnancies or their physical and emotional consequences.<sup>412</sup>

**5.203** When asked about the effect of being infected with HIV on him and his family David stated:

[I]t's just the huge uncertainty with regard to the future and it's something that, other than taking the medication, you really have no control over and you feel that there is a lack of empowerment there because it's not something I can control, as I say, other than taking the medication, and there is the anxiety

---

<sup>407</sup> Ibid, page 145

<sup>408</sup> Ibid, pages 145–146

<sup>409</sup> Day 30, page 147; Letter from David's consultant

<sup>410</sup> Day 30, page 148

<sup>411</sup> Ibid, pages 148–150

<sup>412</sup> Ibid, pages 133–134; David's Witness Statement

every time you attend the appointments of: am I still stable; I feel – well, I don't feel any different but I'm aware that there could be a lead-in time before any symptoms start to show. For as long as I feel well, there is always the hope that treatments are continuing to evolve and ... the carrot out there, that one day they will find a cure for it.<sup>413</sup>

**5.204** Since his diagnosis with HIV, David has only told a couple of friends about it. As a result he and his wife always have a 'feeling of holding back with family and friends'.<sup>414</sup> He stated that living with a secret like that is 'not a way you would choose to lead your life'.<sup>415</sup>

**5.205** David and his wife would be wary about moving away from the area where they live because they have such good support there. It has helped them to have their family close by. David has found the Brownlee Centre at the Gartnavel Hospital in Glasgow, where he is now treated, to be excellent and he has built up a trust with the people there. He is sure that other centres will also be very capable but he is more comfortable dealing with the people he knows. 'I have got to know them and they have got to know me'. This inability to move has affected David's employment prospects. There are more job opportunities in England in the industry in which David works, and it will take longer for him to find suitable employment in Scotland.<sup>416</sup>

**5.206** David has not lost any earnings as a result of his infection with HIV and Hepatitis C. David and his wife funded two attempts at donor insemination, but their daughter's conception was funded by the NHS. Their attempts to have a second child were funded by a combination of David and his wife, the NHS and the MacFarlane Trust. Since 2007 David has received a monthly payment from the MacFarlane Trust. David and his wife have a mortgage, but the life assurance for it is in his wife's name. David has never tried to obtain life assurance as he did not think that it would be an option for him. He is aware that the position with life assurance has altered over the years, and so it is something he may look at in the future. His pension has not been affected by having HIV and Hepatitis C. David stated that it has only been in the last three years that insurance companies have been willing to provide travel insurance to people with HIV. Even then, the insurance premiums are double what they would otherwise be.<sup>417</sup>

**5.207** Dr Seaton provided a written report to the Inquiry. In it, he stated that he was of the view that David's infection with HIV and Hepatitis C had 'hugely affected and impacted on David's family life' as David had described in his witness statement.<sup>418</sup> He further stated:

[H]aving known David since 2000, I have been hugely impressed by his stoical nature, his resolve and his determination to live a fulfilling and normal family life despite the physical and psychological burden of haemophilia and the complicating infections and treatment.<sup>419</sup>

## Elaine

**5.208** Elaine was 66 years old when she gave evidence to the Inquiry. She lives in Fife. Elaine's husband had Haemophilia A. He and Elaine were married in 1964.<sup>420</sup> They have a son.<sup>421</sup> Elaine's husband acquired HIV from his treatment with blood products and died from AIDS, aged 47 years, in 1992.<sup>422</sup> For the purposes of this chapter, Elaine's husband will be referred to as 'Brian'.

### *Brian's haemophilia and his treatment*

**5.209** Brian was the third of four brothers, all of whom had Haemophilia A. There was no family history of haemophilia. The only surviving brother, who was the youngest of the four, also provided a statement to the Inquiry.<sup>423</sup> One brother died, aged 21 years, as a result of a motorcycle accident in the 1960s. The other brother died of AIDS, aged about 52 years, having also been infected with HIV from blood products.<sup>424</sup>

**5.210** Brian's haemophilia was classed as moderate to severe. Hardly a week went by when he did not need treatment for a bleed. The severity of his haemophilia, and the treatment he received for it, were very similar to that of his surviving brother. This brother's haemophilia is also classified as moderate.<sup>425</sup> As a child Brian was treated for bleeds mainly with bed rest, often in hospital. He was also treated with plaster casts. There were times when three of the brothers were being treated for bleeds, each in different hospitals in Edinburgh. Their parents would have to take a taxi to try to visit each of them for 10 minutes during visiting hours.<sup>426</sup> Brian's oldest brother was once in hospital for about six years due to a bleed.<sup>427</sup>

**5.211** Unsurprisingly, due to the disruption caused by his treatment, Brian only managed to attend primary school for a few years. He was then home tutored with his youngest brother instead. He did not attend secondary school.<sup>428</sup> The fact that he was unable to go to school did not bother him. He told Elaine that he thought that he learned more in the hour or two with the tutor, than he would have learned in the classroom. Brian loved being in the fresh air and occasionally swimming. He liked animals.<sup>429</sup>

**5.212** Elaine remembers that, at the time when she and her husband were married (in 1964), most of her husband's treatment for bleeds was bed rest. Sometimes he stayed in bed for four to six weeks. Due to the pain of the bleed, often Brian was unable to bear the weight of the blankets on the area where the bleed was, or even the vibration caused when someone walked across the room. He was provided with a wire cage to take the weight of the blankets. Most of Brian's bleeds were in his knees.<sup>430</sup>

**5.213** In about 1969 Brian's brother received his first treatment with factor concentrate, and it is likely that Brian received this treatment around then too. Brian and his brother thought that this treatment was a miracle cure as it shortened the time a bleed lasted. Also, Brian could often sense when a bleed was starting. When this happened, he either

<sup>430</sup> Ibid, pages 119–120

rested, or obtained treatment with factor concentrate as quickly as possible to keep the bleed and its effects to a minimum.<sup>431</sup> As the factor concentrate worked so well, Brian started going to the hospital more often to receive treatment for a bleed.<sup>432</sup>

**5.214** During the 1970s and the early 1980s Brian's treatment for bleeds consisted of a mixture of both cryoprecipitate and Factor VIII. He also received blood products when he underwent dental treatment. He was treated at the Royal Infirmary of Edinburgh (RIE). The amount of treatment he needed varied from year to year, but it was usually at least twice a month.<sup>433</sup> At some time Brian started home treatment. Elaine could not remember when this was but it seems likely it was around the early 1980s.<sup>434</sup> Brian was warned, in general terms, about the risk of a hepatitis virus.<sup>435</sup> Between 7 March and 19 August 1984, Brian was treated on 11 occasions with the HIV-infected batch number 0090 of Factor VIII.<sup>436</sup>

### *Brian's diagnosis with HIV*

**5.215** In the summer of 1984, Elaine went on a trip to Canada. While she was there she read an article in a newspaper about a person with haemophilia having contracted HIV as a result of receiving contaminated blood products. Elaine had already heard through the media about HIV, but this was the first time she had heard of a person with haemophilia contracting the virus. Elaine cut the article out of the newspaper and brought it home to show her husband. When he saw it on her return in July 1984, Brian 'completely dismissed it'. He told Elaine that that could not happen in Scotland as Scotland produced its own blood products. He was sure that the blood product, which the person described in the article had received, was commercial blood from either drug addicts or prisoners.<sup>437</sup> At this point, unknown to himself, Brian was already infected with HIV. He was later found to have been HIV-positive on 29 May 1984.<sup>438</sup>

**5.216** In late 1984 Brian received word from the Haemophilia Society about practising safe sex. He and Elaine were unsure why they were being told about this, particularly as they had been married 20 years by then. Towards the end of 1984, Brian, by himself, attended a meeting of other haemophilia patients and Professor Ludlam at the RIE. He later told Elaine what had happened at the meeting 'word for word'. Elaine told the Inquiry that the doctors at the meeting were asked by those present if HIV could be transmitted through blood products. The doctors told everyone there not to worry. 'They were still maintaining that it was coming through the gay community. The doctors said 'We are only telling you about this virus but it won't affect you.' Brian stood up at the meeting and said, 'Of course it won't affect us. Scotland makes its own.' One of the doctors told him that they had been given 'not home grown stuff'. Brian was very angry when he heard this and told the doctors 'they had no business giving them stuff from abroad'. He asked the doctors why they had not been told about this. The doctors told them that Scotland was running low and they had to give the patients something.<sup>439</sup>

<sup>437</sup> Day 31, pages 132–134

<sup>438</sup> Letter from Brian's consultant. Early kits that tested for antibodies to HIV became available on an experimental basis in October 1984, and Brian's blood sample given in May was retrospectively found to be positive.

<sup>439</sup> Day 31, pages 134–137; Although this may have been Brian's understanding of what was said at the meeting, this was not what patients were told at this meeting. The details of this meeting are narrated in Chapter 33, *An Investigation into the Systems in Place for Informing the Patients about the Risks – HIV/AIDS*, paragraphs 33.221–33.252

**5.217** In December 1986 Brian arranged an appointment with the Haematology Department so that he, Elaine and their son could be tested for HIV. Elaine thought that he arranged the appointment as more and more information was coming out in the press, and from the Haemophilia Society, about people with haemophilia being infected with HIV. As a result, Brian became increasingly concerned about the virus. Elaine stated that her husband was not worried about himself, only about her and their son. At the appointment in December 1986 the doctor advised them that there was no need for their son to be tested, but Brian insisted that they were all tested. About a week or two later Brian returned alone for the results of the blood tests. The doctor told him that his family was 'okay'.<sup>440</sup> Brian took this to mean that all their results were negative, but the doctor said to him 'You are not asking about yourself'. The doctor then told Brian that he was HIV-positive.

**5.218** The doctor told Brian that the virus might not develop into AIDS.<sup>441</sup> When Brian returned home after being diagnosed with HIV, he was upset, but relieved for Elaine and their son. Neither Brian nor Elaine knew much about HIV. Elaine commented, 'We had no idea what we were in for'.<sup>442</sup>

**5.219** Brian realised that the doctors had known that he was HIV-positive before he had asked to be tested for it. This made him angry; he realised that he could have transmitted the virus to Elaine while the doctors were aware that he had been infected. When Brian asked a doctor (Elaine was unsure who the doctor was) why he had not been told sooner that he was HIV-positive, he was told that Professor Ludlam did not like telling people that they were infected and patients would be told that they were HIV-positive only if they asked about it.<sup>443</sup>

**5.220** After his diagnosis with HIV, Brian and Elaine continued to live life as before. Brian very rarely managed to work due to his haemophilia. He was classed as disabled and had a 'green card'. They lived in a small community which meant that most people knew him. He used to try to persuade potential employers that he was fit for work, but most employers were unwilling to employ someone with haemophilia. He sometimes managed to obtain labouring work which was not recommended. Elaine did not work either, but their son, who was still living at home at the time, did work.<sup>444</sup>

**5.221** In the late 1980s Brian was referred by Professor Ludlam to Dr Alison Richardson, a Clinical Psychologist, for counselling in respect of his diagnosis with HIV. Initially he was reluctant to meet with her, but eventually he did so. He found his meetings with her helpful. She was able to tell Brian and Elaine what his symptoms of HIV might be. Until she did so, Elaine stated, 'we were just in the dark'.<sup>445</sup> At one point Brian spoke to Dr Richardson about suicide. Dr Richardson was very supportive to both him and Elaine and continued to see Elaine after her husband died.

**5.222** In her evidence to the Inquiry, Dr Richardson stated that during the group counselling sessions of the patients with haemophilia and HIV, a number of topics were discussed. These included anger against the Blood Transfusion Service and Professor Ludlam, suicide,

<sup>445</sup> Day 31, pages 148–149

wills, funerals, loved ones watching them all the time for symptoms, being irritable with family, sexual anxieties and alcohol problems.<sup>446</sup> She stated these patients, 'were understandably very anxious about what was going to happen to them, and of course at that time it was very, very unclear what might happen'.<sup>447</sup>

**5.223** Elaine is unsure what her husband was told about the risk of transmission of HIV. After he was diagnosed with HIV, they stopped having a sexual relationship. She tried to reassure him, but he was so 'paranoid and petrified of infecting [her] that [that] side of [their] marriage was over forever'.<sup>448</sup>

**5.224** A further impact of Brian's diagnosis with HIV was that, for a period of about six months, he started to drink more. Before he did not drink much alcohol, having only a whisky or a stout if they went out at the weekend. Brian used to prefer being outside and being with his animals which Elaine thought stemmed from being ill so much.<sup>449</sup> After his diagnosis with HIV, Brian started drinking more whisky when they went out and then 'his personality changed altogether'.<sup>450</sup> He became very argumentative. Elaine and their son bore the brunt of this, and Elaine found it very difficult to cope with. She realised that the excessive drinking was her husband's way of coping with his diagnosis and the fear and frustration it caused him. She stated that it was terrible to see her husband's personality change in this way, and she repeatedly reminded herself that this was not her husband. Their son also suffered as a result of this. He was still living at home at the time. He tried to be understanding of his father, but he did not wish to see his mother or his father hurt.<sup>451</sup>

**5.225** Brian and Elaine did not know how to tell people about his diagnosis with HIV, and they told very few. Brian told one good friend that he was HIV-positive. A couple of weeks later at New Year, Brian gave the friend's grandchild a kiss. The friend told Brian never to kiss his grandchild again. Brian was very distressed by this. Elaine stated that he 'completely broke down'.<sup>452</sup> Brian was also concerned for his son. He worried about how his girlfriend at the time would react. Brian did not want 'anything coming back on [his son]'.<sup>453</sup> They spoke to Dr Richardson about this; she told them that as they lived in a small community she did not know if that would work for them or against them. After the reaction of his friend, Brian did not want to tell anyone else that he was HIV-positive.

### *Brian's symptoms of HIV*

**5.226** The Inquiry tried to recover Brian's medical records to assist Elaine's evidence, but unfortunately NHS Lothian was unable to locate them.<sup>454</sup> Instead, it provided two pages of data stored on a historical database.<sup>455</sup> Elaine and Professor Ludlam were able to provide copies of some excerpts from Brian's medical records which assisted the Inquiry. It was explained to the Inquiry that the copy records provided by Professor Ludlam came from a separate filing system, in which blood treatment records at the RIE were maintained.<sup>456</sup>

<sup>455</sup> Excerpts from data received from NHS Lothian in respect of Brian

<sup>456</sup> Email from Central Legal Office to the Inquiry dated 7 June 2011

**5.227** Elaine stated that her husband's first symptoms of HIV were loss of appetite and weight-loss. She thought that he had these symptoms for a couple of years before he was diagnosed with the virus.<sup>457</sup> It is possible, having seen the limited medical records available for Brian, that he may have been found to have persistent generalised lymphadenopathy in August 1985.<sup>458</sup> Elaine remembered that his lymph nodes were checked. As this was before Brian discovered that he was HIV-positive, it seems likely that he was not told about this. In April 1989, Brian was prescribed 'irregular' Pentamidine, suggesting that he may also have suffered from some symptoms of pneumonia.

**5.228** In June 1990 Brian developed PCP. He and Elaine were supposed to be going to Ireland to stay in a caravan owned by the Haemophilia Society, but Brian had to be admitted to hospital instead. Elaine remembers he had chest problems, such as breathlessness, and that he was quite 'chesty'.<sup>459</sup> Brian was treated in hospital and recovered from PCP. Elaine remembers that he was told that he was lucky to recover as, a few years before, HIV patients usually died soon after developing PCP. At this time Brian started treatment with Zidovudine and prophylactic treatment for PCP.<sup>460</sup> Elaine was unsure if he suffered from any side-effect of these medications.<sup>461</sup>

**5.229** Despite this prophylactic treatment, Brian developed PCP again in January 1991. He was admitted to hospital for treatment. His dose of Zidovudine was increased and he was prescribed Pentamidine. Elaine stated that while her husband was in hospital the consultant haematologist treating Brian tested him for PCP, and told him that if the result was positive he had developed AIDS. At Brian's request this doctor agreed to tell him the result of the test that night. Elaine stated that her husband 'was in pieces'.<sup>462</sup> Instead of the same doctor returning with the result, a younger doctor came. This doctor told Brian that he had developed AIDS and walked out of the room. Brian was very upset to be told that he had AIDS by a doctor he did not know, and in what he considered to be such a callous manner. Later the consultant haematologist apologised to Brian for not having given him the result himself.<sup>463</sup>

**5.230** After this, Brian's condition deteriorated, and 'his body started to give out'.<sup>464</sup> He became very tired. He developed a rash on his face. He suffered from diarrhoea.<sup>465</sup> In April 1991 he was diagnosed as having HIV-wasting. In July he developed oesophageal candidiasis (a fungal infection of the oesophagus). His treatment with Zidovudine was stopped in November 1991 due to cytopenia (a deficiency of cellular elements of the blood), a known side-effect of Zidovudine. His treatment with Zidovudine was restarted in December that year.<sup>466</sup>

**5.231** Brian developed a lot of infections. He had to have a nasogastric tube inserted for feeding. Elaine became his carer, and did everything for him. Brian preferred only Elaine to care for him. He used to say, 'I don't need help, my wife will do it'.<sup>467</sup> Occasionally Brian's

<sup>466</sup> Ibid, page 162; Excerpts from data received from NHS Lothian in respect of Brian

<sup>467</sup> Day 31, pages 162–163

GP came out to visit him, and the local nurse came every Monday. Dr Richardson used to visit them and give them advice. Initially their home did not have a shower, and a bath-chair was installed so that Brian could have a bath. He needed Elaine's help with bathing, and once joked to her that he would die of pneumonia not HIV, due to the length of time she took helping him into the bath.<sup>468</sup>

**5.232** Brian became good friends with a 30-year-old man with haemophilia who had acquired HIV, and who lived quite close to him. This friend died a couple of months before Brian, and Elaine said 'his death broke Brian's heart'.<sup>469</sup> In January 1992 Brian returned from a hospital appointment and broke down. He told Elaine that he had been told that he only had six weeks to live. In fact he had not been told this, but he was very upset about his friend's death. He had told the nurses at the hospital that he would die next, and that he had only about six weeks to live. The nurses told him that he had at least another year. Elaine reminded her husband that he had promised her that he would keep fighting. He replied, 'I'm not giving in ... I'm tired'.<sup>470</sup>

**5.233** Brian died at home about five weeks later on 8 February 1992. Before his death, he asked Elaine that his body be kept in the house before it was cremated. When the undertaker came to the house, Elaine felt she had to tell him that her husband was HIV-positive. At that point the undertaker said that he was unable to prepare her husband's body himself, and that his body would need to be taken away. Their son and Brian's brother put Brian's body into a body-bag and it was taken out of the house. Elaine did not know where her husband had been taken. She wished to visit him but the undertaker would not tell her where he was. Elaine stated that 'to this day nobody has told me where my husband went to'.<sup>471</sup> She stated:

I always have felt, and always will feel, that I broke my promise to [my husband]. [He] never asked for much – just to be with his family – and they even took that away and put him in a strange place completely on his own. It was bad enough for him to die like that but to be treated like a leper and without any dignity, he certainly didn't deserve that.<sup>472</sup>

**5.234** After Elaine gave evidence the Inquiry carried out some investigations to ascertain where her husband was taken after he died. The Inquiry found out the details and passed this information to Elaine.

**5.235** Brian had asked the doctors not to put AIDS on his death certificate and so the cause of his death was listed as septicaemia, pneumonia, immunosuppression and haemophilia.

**5.236** About a year after Brian's death, Elaine asked to be tested again for HIV before she was admitted to hospital for a minor operation. The result of this test was negative.<sup>473</sup> Elaine felt guilty that she was not HIV-positive, 'why did [he] have it and why did I escape?'.<sup>474</sup>

**5.237** In late 2002 Elaine heard from the Haemophilia Society that haemophilia patients who were HIV-positive were very likely also to be infected with Hepatitis C. Elaine asked her GP to test her for Hepatitis C. The result of this test was negative. At a meeting with

<sup>471</sup> Ibid, pages 168–169;

<sup>472</sup> Elaine's Witness Statement

<sup>473</sup> Day 31, page 167

<sup>474</sup> Ibid, page 170

Professor Ludlam in January 2003, Elaine was told by him that her husband had also been infected from blood products with the virus that causes Hepatitis C. A blood test result, dated 13 January 1992, had confirmed that he was positive for the antibody to HCV. Elaine is sure that her husband did not know that he had been infected with Hepatitis C; if he had known he would have told her.<sup>475</sup> By mid-January 1992, Brian was a very sick man and he died less than a month later from a different infectious disease. His condition at that time may explain why Brian was not informed of the test result by those then treating him. At that meeting she expressed concern that she had been at risk of acquiring the virus from her husband, and no-one had warned her or advised her of the measures she could take to avoid infection. Professor Ludlam indicated that the risk of transmitting the virus through sexual contact was low.<sup>476</sup> Nevertheless, Elaine felt that she should have been informed in 1992 of her husband's hepatitis diagnosis as she might herself, by that time, or before, have contracted the virus from her husband. If she had done so, she would, without her knowledge, have suffered the effects of the virus until 2002 when she went to her GP for Hepatitis C testing in consequence of the information she had received from the Haemophilia Society.

**5.238** Elaine has suffered from anxiety and depression since the 1980s. Following her husband's death, in March 1992 Elaine was diagnosed with reactive depression. This persisted and she was deemed unfit for work until at least 1998. During 1992, Elaine attended counselling but she did not wish to take medication. Since then Elaine has been seen by her GP on a fairly regular basis. On occasion she has been prescribed various different antidepressants which Elaine has taken for a while, and then discontinued. Elaine stated that she did not want to become dependent on pills, and so she tried to work through her mental health problems herself. In August 1998 Elaine was noted to be 'verging on panic attacks'. In 2000, Elaine was noted to be concerned that she was infected with Hepatitis C, but she was found to be negative for this. She was prescribed a further dose of antidepressant therapy in 2002, on the tenth anniversary of her husband's death, and has been prescribed such therapy intermittently since then. She was last prescribed antidepressant therapy in September 2009.<sup>477</sup>

**5.239** Elaine stated that her son is 'a very deep person'.<sup>478</sup> She believes that he has been very affected by having to assist with putting his father into a body-bag. After his father died, he told Elaine that he was going to do what his father had asked of him before he died and marry his girlfriend. They married soon after. A year or so after Brian's death, her son's wife came to Elaine and told her that her son was not speaking to her. Elaine believed that her son's behaviour was due to his father's death. When her son heard that Elaine had made contact with the Inquiry, he advised her to 'forget it all'<sup>479</sup> but before she came to give evidence he offered her any help she needed.

**5.240** In October 1990 Brian's GP told him that he should make a claim for Special Attendance Allowance. The GP told him that he would state on the appropriate form that he expected Brian to die within six months. It proved very difficult for Brian to be awarded this benefit, but finally, in August 1991, after Brian underwent a medical examination while he was an in-patient in hospital, he was awarded the higher rate for day and night

care instead of the allowance awarded to those who are terminally ill. While Brian was alive he received money from the MacFarlane Trust. When he died, Elaine was paid £1000. She was also paid a widow's allowance of about £100 a month which she still receives.<sup>480</sup>

## Mark

**5.241** Mark was 41 years old when he gave evidence. Mark used to work as a cabinet maker. He was medically retired in 1997. Mark has Haemophilia A and contracted both HIV and Hepatitis C from blood products.<sup>481</sup>

### *Mark's diagnosis with haemophilia and his treatment*

**5.242** In 1970, when Mark was a baby, he fell and cut his lip. His lip continued to bleed and 10 days later he was admitted to the local hospital in England, where the family then lived. On examination Mark was very pale. Tests revealed that he had mild Haemophilia A. He was treated with blood, fresh frozen plasma and cryoprecipitate and discharged home after two days in hospital.<sup>482</sup>

**5.243** In 1972, Mark and his family moved permanently to Scotland, and thereafter lived at various locations. Mark was treated with cryoprecipitate when he was two and a half years old when he bit his tongue, again when he was seven years old for a bleed in his right elbow secondary to trauma, when he was eight years old due to a bleed in his right knee and when he was nine years old due to a further bleed in his right knee.<sup>483</sup>

**5.244** In 1979, Mark and his family moved to an address in the countryside. Mark was referred to a consultant haematologist at the Royal Infirmary of Edinburgh (RIE), in respect of his haemophilia. Further investigations at the RIE revealed that Mark's Factor VIII level was only 2.2% which meant that his haemophilia was, in fact, moderately severe. His mother's Factor VIII level was found to be 34% which meant that she was likely to be a carrier of haemophilia. It was noted that Mark's right knee was swollen with a small degree of fixed flexion. Mark's right knee became one of his target joints (a joint where there is regular bleeding).<sup>484</sup>

**5.245** Mark received treatment for his haemophilia at his local hospital as it was too far for him to travel to Edinburgh on a regular basis. The amount of treatment Mark received increased substantially. He stated, 'Now that they knew what was wrong with me, it was not a case of just rest and relax, it was off to the hospital for assessment'.<sup>485</sup> Between 18 April and 5 June 1980 he was treated with cryoprecipitate on three separate occasions, each occasion involving treatment in the local hospital over a number of days. Mark's mother started administering his treatment herself.<sup>486</sup> Between 5 June and 4 August 1980 Mark was treated with cryoprecipitate on six separate occasions.<sup>487</sup> As well as attending his local hospital for treatment, Mark also attended the Haematology Department of the RIE every three months for review.<sup>488</sup>

<sup>487</sup> Day 32, pages 101–102; Excerpts from medical records recovered in respect of Mark

<sup>488</sup> Day 32, pages 103–104

**5.246** In 1981 Mark's mother was taught how to administer Factor VIII. Mark was treated with Factor VIII at home when he had a bleed or after a severe bleed to prevent it recurring. In about 1983, when Mark was 14 years old, he began treating himself with Factor VIII. He stated that this did not make the treatment hurt any less, but concentrating on what he was doing served as a distraction. Mark and his mother used to keep detailed records of the treatment he took at home. These were handed back to the hospital. A record of treatment Mark took in 1984 showed that he was treated with the HIV-infected batch of Factor VIII numbered 0090 between 25 March and 27 April 1984.<sup>489</sup>

**5.247** Mark's haemophilia had a significant effect on his childhood. Living in the country he enjoyed the outdoor life. He used to help his parents. He developed a bleed after cutting nettles with a small scythe, and chopping logs with a full-sized axe. He was advised by his local doctor that it was unwise for him to use such instruments, and so he had to stop these activities.<sup>490</sup> Mark did not enjoy primary school and it seems that his haemophilia was a major factor in this. He stated that after it was 'announced' that he had a bleeding disorder, the other children used to push or shove him and ask him why he was not bleeding.<sup>491</sup> In secondary school, he was singled out as being 'rather weak and feeble'.<sup>492</sup> He was not allowed to take part in games and used to have to go to the library instead. He stated 'for certainly the first year, there was an element of being pushed around and bullied'.<sup>493</sup> This stopped when Mark stood up for himself in a fight with another pupil. Mark missed a lot of school due to bleeds. Soon after starting secondary school, he developed further bleeds in his right knee. He spent a lot of time in hospital before his O-grade exams. His teachers told him that, as a result of this, he did not need to sit his prelims or the O-grades. Mark thought that he should sit the prelims and so he did. He 'failed everything quite spectacularly'.<sup>494</sup> After this, he worked harder and passed all his O-grade exams except one. He left school with six O-grades and one Higher grade. He believed that his exam results were also affected by teachers' strikes which happened around the time of some of his exams.<sup>495</sup>

**5.248** In about 1983 or 1984, Mark watched a television programme with his family which talked about the spread of a 'horrific virus that was going to wipe out a quarter of the world's population', HIV.<sup>496</sup> The programme stated that the virus had infected drug users and homosexuals. It also mentioned that another category of people at risk was those who used blood products and those at the highest risk were people with haemophilia. On hearing this, Mark panicked and found himself unable to breathe properly. He had to leave the house.<sup>497</sup>

**5.249** Mark continued to attend clinic appointments at the Haemophilia Centre at the RIE. He was accustomed to regularly giving blood samples at these appointments.<sup>498</sup> His mother accompanied Mark to these appointments until about 1986.<sup>499</sup> Mark and his parents were warned of the risk of infection from blood products, including the risk of HIV and the risk

<sup>489</sup> Ibid, page 107; Excerpts from medical records recovered in respect of Mark; thus Mark was a member of the 'Edinburgh Cohort' – See Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paragraphs 10.16 onwards

<sup>499</sup> Ibid, pages 114 and 116

of NANB Hepatitis. It was emphasised to them that Mark was being treated with blood products 'from Edinburgh' and not commercial blood products. The fact that the treatment he was receiving was produced locally was emphasised to a high degree. He said that doctors always stressed that he was being treated with factor concentrate manufactured in Edinburgh, not with commercial factor of foreign origin, and that continuing to take local factor was the safest option and reduced the risks.<sup>500</sup> Mark and his parents felt reassured by this.<sup>501</sup> Mark described going down to England to stay with his grandparents and being given letters stating that he was only to be treated with local Factor VIII, which he could hand over in the event that he had to attend a hospital.<sup>502</sup> Mark did not know whether his parents went to the meeting about HIV infection held at the RIE in December 1984.<sup>503</sup>

**5.250** After leaving school, despite being advised to find an office-based job, Mark started training in joinery and cabinet making. With help from a Government enterprise allowance scheme, he set up his own cabinet-making business. He continued to attend the Haemophilia Centre at the RIE for monitoring and treatment of his haemophilia.<sup>504</sup> Mark said that, after 1986, when he attended for his three-monthly clinic appointments the doctor would want to discuss his blood test results. It was either Professor Ludlam or Dr Dennis he saw at the clinic appointments.<sup>505</sup> He said that there would be discussions, often using technical terms such as red blood cells and white blood cells, which did not mean anything to him at his age.<sup>506</sup> He knew at the time that they were testing for things like HIV and hepatitis. He knew that there was a small risk of infection and assumed that the doctors would keep an eye on things to see if he had caught anything. He did not know about HIV infection in other patients.<sup>507</sup> He continued to rely on his doctors, upon whom he had relied for years, and assumed that they would tell him if there was anything amiss.<sup>508</sup> He would be asked whether he wanted to know the results of his tests and said that he would reply, 'Tell me if there's anything wrong.' The doctor would then close the file and say, 'See you in three months.'<sup>509</sup>

**5.251** Before giving evidence, Mark had been made aware that Dr Bernadette Auger had noted in his RIE records for 20 March 1989 that he was: 'Aware we have been doing HIV tests – DOES NOT WANT TO KNOW THE RESULT.'<sup>510</sup> The latter part of this quote had a star in the margin next to it. The full note described his examination results, including observations of swelling in his left elbow and small nodes in both armpits, and continued:

I have told him that if he ever wants to discuss his HIV results, he can contact one of the doctors in the centre and arrange to see them at any time. I have advised him to assume that he is at risk of passing on HIV infection and therefore should use protection for intercourse and be especially careful with the disposal of needles and blood spillages.<sup>511</sup>

<sup>509</sup> This does not accord with the evidence of the doctors. It is discussed in more detail in paras 33.304–33.307 and 33.401–33.404 of Chapter 33, *An Investigation into the Systems in Place for Informing the Patients about the Risks – HIV/AIDS*; Mark's witness statement

<sup>510</sup> Mark's witness statement; Excerpts from Mark's OP clinical notes

<sup>511</sup> Excerpts from Mark's OP clinical notes

**5.252** The note continued that he was referred to the Haemophilia Society for the most recent information concerning possible loans for house purchases, in which he was interested. Mark's response to the note in oral evidence was:

Well, yes. I knew I was being tested for HIV but I would have expected a doctor to have actually informed me if there is anything wrong. So when they say, "Do you want to know the results of your tests," I was expecting it to be a whole list of information that ... didn't really mean very much to me. So again, knowing that HIV was a risk, I would have automatically assumed, for the medical practitioners that I trusted and relied on, they would tell me if anything as monumentally wrong as being infected with HIV – I would be automatically informed.

So, as I say, my assumption is the blood test results would be red blood cells, white blood cells and the levels of what is in my blood, not a virus

....

The other thing ... about looking at buying a house. If I had any inkling of what was wrong with me, why would I be buying a house? So does that not indicate that I had no idea that anything was wrong with me? If I'm discussing the possibility of buying a house or a flat, if I was HIV positive, knowing that HIV in those days was classified as a fatal condition, that if you have HIV you will be dead in three or five years; if I suspected I had HIV, why on earth would I be looking at buying a flat or a house?<sup>512</sup>

**2.253** Mark was told that there were other entries in the records to the same effect as Dr Auger's and was asked whether it was possible that the doctors had formed the impression that he did not want to know, although his own recollection was evidently different. Mark simply repeated his answer that when his doctors asked whether he wanted to know the results he invariably answered: 'Tell me if there is anything wrong'.<sup>513</sup>

**5.254** Asked whether he thought, on the basis of Dr Auger's note, that the doctors and social workers at the hospital may have thought that he did not want to know the results of the test, Mark replied:

But why should I – should they not tell me? If something is seriously wrong with a patient, is it not their job as a trained practitioner to help and assist the patient? So if there is something wrong – if you went to see a GP and the doctor found you had cancer or something – "We won't tell him just now. We don't want to spoil the weekend." You wouldn't consider that fair, would you?

On that basis I would have assumed if they knew I was HIV positive but they deliberately did not tell me and as I have subsequently discovered, they didn't tell me but they were publishing it in the Lancet from 1985, I believe. So they are telling the rest of the world and the medical fraternity but they don't have the manners or conscience to tell the actual victim who is infected.<sup>514</sup>

---

<sup>512</sup> Day 32, pages 122–123

<sup>513</sup> Ibid, page 122

<sup>514</sup> Ibid, page 124

**5.255** In his statement, he said:

If at this time the doctor was trying to inform me that I had HIV I certainly did not appreciate what he was implying. It was discussed with me on more than one occasion about the risks of passing on HIV infection and to use protection for sexual intercourse. However, I took this to be more of general guidance of how things should be done.<sup>515</sup>

### ***Mark's diagnosis with HIV***

**5.256** In January 1991, when Mark was 21 years old, he was told by Professor Ludlam that he had been infected with HIV. He described the disclosure in these terms:

I saw Dr Ludlam at a regular clinic appointment in 1991 when I would have been 21 years of age. I hadn't seen him for a while as it had been Dr Dennis I had been seeing. I was having regular bleeds in my right knee and joint damage. My knee and other bleeds were discussed at this appointment. There was an awkward pause and then Dr Ludlam said to me, "It has come to my attention that you were one of the few unfortunates to be infected with HIV. You have been infected for a number of years and you will be dead within a year." I was absolutely stunned. I was aware that there was a risk of contracting HIV but had been told that blood products from Ellens Glen [ie SNBTS products] were the safest you could get. The nurses at the haemophilia centre had said this and had also discussed safe sexual intercourse with me. Dr Ludlam informed me that I was entitled to an ex-gratia payment to help me through the last few months of my life. He said to qualify for this payment all I had to do was to sign here and here. There was no one else present at this meeting other than me and Dr Ludlam. After giving me this information he then said that the offer of the ex-gratia payment would be withdrawn unless I agreed to this in the immediate future and then I would get nothing. This was the Macfarlane Trust payment. He said if I signed the money would be in my bank account within a week. He said go out and enjoy yourself. I am now aware that Dr Ludlam shouldn't have given me such news without someone of my choice accompanying me and he also should have had someone present. I was not offered any counselling.<sup>516</sup>

**5.257** In oral evidence, Mark agreed that his immediate reaction was just to 'get away':

I believe it was three lots of documents I had to sign and I believe I received counseling and there was other discussions. Again, you are in a stunned condition. Your world has just been smashed to pieces and I do remember wanting to be out of the hospital as soon as possible.<sup>517</sup>

**5.258** Professor Ludlam's notes of this appointment were read to Mark. They commented that the hospital had 'at last managed to persuade (him) to come for review'. They noted:

I have told him of his HIV status. He had not really suspected that he might be positive and he was therefore quite taken aback. Does not wish to tell anyone at present. To see Mrs Brown today. Review one week.<sup>518</sup>

---

<sup>515</sup> Mark's witness statement

<sup>516</sup> Ibid

<sup>517</sup> Day 32, page 126

<sup>518</sup> Excerpts from Mark's OP clinical notes

**5.259** Mark's final comments in oral evidence returned to this event:

I suppose the thing that I remember is how my world was smashed into a million pieces from one sentence, when Ludlam told me what the situation was; that was my world effectively over, plus the fact that the outcome of being – you know, “You have been infected for a number of years, you will be dead within a few months” is a very difficult thing to live with and seems very harsh and unfair when you have worked very hard and made a lot of effort to achieve a lot of things that I was told I wouldn't be able to do.<sup>519</sup>

**5.260** He thought that immediately after seeing Professor Ludlam he saw Mrs Geraldine Brown, the hospital social worker. He had met her on a number of occasions previously. Mark was asked whether he had seen Dr Alison Richardson. He thought that was later: she told him that she had been watching him on paper for thirteen years before they met and that there had been a lot of interest in his case.<sup>520</sup> Mark agreed to undergo further HIV tests. He then wanted to get away from the hospital as quickly as possible.<sup>521</sup> He cannot remember what he did directly after that appointment.<sup>522</sup>

**5.261** Mark had obtained his medical records some seven years before giving oral evidence.<sup>523</sup> He said that he then discovered that he had been infected with HIV in 1984, although he was part of Professor Ludlam's 'AIDS study' from 1983. He referred to a positive HIV test report in his medical records dated 18 January 1988.<sup>524</sup> Mark added:

From information I have received I am number 15 in Professor Ludlam's selection. He has published articles in the *Lancet* in 1985 and defines myself and others as his 'unique group'.<sup>525</sup>

**5.262** Due to the stigma surrounding HIV Mark told nobody, not even his parents, of his diagnosis for eight years: 'I effectively lived a lie'.<sup>526</sup> He stated:

In those days, the ... programmes on the television were gravestones falling down, and if you shake hands with somebody who is HIV positive, a quarter of the population will be dead.<sup>527</sup>

**5.263** Mark stopped buying newspapers. He stopped socialising: 'I basically stopped doing things'.<sup>528</sup>

**5.264** Professor Ludlam referred Mark to the Western General Hospital in Edinburgh for treatment of his HIV. Initially, Mark refused to attend as he did not see the point. He realised that he had been infected with the virus for a number of years. He assumed that the life expectancy of a person with HIV was three to five years and so he thought that he had only months to live.<sup>529</sup> He stated:

<sup>525</sup> Mark's Witness Statement; Professor Ludlam's evidence in relation to this aspect of Mark's evidence is detailed in paragraphs 33.305–33.307 of Chapter 33, *An Investigation into the Systems in Place for Informing the Patients about the Risks – HIV/AIDS*; The issues raised by Mark's evidence are discussed in paragraphs 33.401–33.404

<sup>526</sup> Ibid

<sup>527</sup> Day 32, page 133

<sup>528</sup> Ibid, page 133

<sup>529</sup> Ibid, pages 133–134

I do recall being sent information which I would put in the car, drive out into the middle of the countryside, read through everything I possibly could and then, the paranoia was to the extent that I would then shred it and burn it so there was no evidence. And it was the same when they suggested medication and again, would it cure it? No. So what's the point? And I refused everything.<sup>530</sup>

**5.265** Mark carried on working as normal and spent 18 months of 'relaxation and leisure'.<sup>531</sup> He received £22,500 from the MacFarlane Trust and spent it on the biggest and fastest motorcycle he could find. He found this a good way to let off steam and 'rode it like a lunatic'.<sup>532</sup> One of his friends warned him that he would need to calm down or he would kill himself. Mark stated, 'I would have actually seen that more as a bonus than a minus because if I had died in a motorcycle accident, it may have turned out that no one would ever know what happened'.<sup>533</sup> He felt extremely stressed and also a mixture of frustration, anger and despair:

I carried on as though everything was perfectly all right until you shut the front door and then it's back to utter despair and the end of the world, and that went on for years.<sup>534</sup>

**5.266** As he shared a flat with others and worked in a workshop with three other people, Mark was very reluctant to take any medication. He did not wish anybody to find out and ask him what the medication was for. The only medication Mark took was Septrin, which is the trade name for Co-trimoxazole, as prophylactic treatment for PCP. Mark suffered diarrhoea as a result of taking this medication. In about November 1993, Mark ran out of Septrin. His diarrhoea resolved and so he stopped taking it.<sup>535</sup>

**5.267** In 1993, Mark was lodging with a couple in a small village. One evening there was a programme on television about people with haemophilia having AIDS. Mark did not watch it. Immediately after the programme finished the couple came to his room and told him what the programme had said. He described this as '[a] very awkward moment'.<sup>536</sup> Mark pointed out to them that the media were trying to horrify people, and that they should not believe everything they heard. He told them that the programme was mainly about people in England and that he had received blood products from Scotland which were considerably safer and meant that the number of people affected was fewer. This appeased one of them but the other said, 'You haven't answered the question: do you have AIDS?' Mark replied 'No, I don't have AIDS at the moment. I'll let you know if I do'.<sup>537</sup> At that point Mark did not know whether he had AIDS or not so, having been brought up not to lie, he considered he was not lying to them. A few years later he returned to visit the couple and the woman told him that a couple living down the road from her had AIDS. As a result of this she would not let their son play in the garden. Seeing how paranoid she was about HIV, Mark was very relieved that he did not tell them that he was HIV-positive. He is still friendly with this couple and they still do not know that he has HIV.<sup>538</sup>

<sup>537</sup> Ibid, page 138

<sup>538</sup> Ibid, page 139

**5.268** Mark attended the Haemophilia Centre for review in December 1993. The records of that appointment state that Professor Ludlam's clinical assistant had a long discussion with Mark about Hepatitis C as he had been found to be antibody positive. They record that Mark was given an information leaflet on Hepatitis C and invited to attend the joint liver clinic run with a consultant hepatologist. Mark recalled discussions about different medical matters but he was unable to recall when they took place. He believed that the first time he was made aware that he had Hepatitis C was in 1997. At this appointment it was also noted that he was feeling 'very well at present, has a good appetite and no specific symptoms'.<sup>539</sup> Mark's GP was a family friend, and was also Mark's parents' GP. Mark was so concerned about confidentiality that, for a period, he stopped being registered with a GP.<sup>540</sup>

**5.269** In June 1995 Professor Ludlam wrote a letter to the Benefits Agency advising it that, as a result of many bleeds into his right knee, Mark now had very pronounced arthritis. He stated that the progressive arthritis in Mark's knee was of sufficient severity that Mark was unable to continue with his work, and that the arthritis was permanent.<sup>541</sup> Despite this, Mark continued to work. The business became less lucrative as, over the years, customers started to haggle over the cost of his work. This resulted in Mark working longer hours, sometimes working nearly 18 hours a day.<sup>542</sup>

**5.270** In November or December 1995 Mark developed a rash affecting his trunk and forearms. This was treated to good effect with Canesten cream (an antifungal treatment).<sup>543</sup>

**5.271** On 9 December 1995, while machining wood, Mark severed the end of two of his fingers. The wife of a man who worked in a nearby workshop was a district nurse. She offered to assist Mark. She tried to examine Mark's hand but, due to his concern about the risks from his blood, Mark would not allow her to do so which caused her some offence. Mark was driven by the man to a local cottage hospital. He was then transferred by blue-light ambulance to another hospital where, under general anaesthetic, the ends of his middle and ring fingers on his left hand were amputated.<sup>544</sup>

**5.272** In July 1996, Mark attended the Haemophilia Centre with a recurrence of the rash which he had at the end of the previous year. The rash was on both arms and on his left thigh. It presented as 3cm diameter circular patches with raised margin and clear centre. It was itchy. It was thought to be caused by a fungal infection. Mark was prescribed more Canesten cream.

**5.273** Mark's financial situation remained difficult. His income from the business was low. In addition to this Mark received a monthly payment of £80 from the MacFarlane Trust as well as mobility allowance. Mark remained very concerned about the stigma surrounding HIV, and still did not confide his HIV status to any family or friends. He believed that if it was known where he lived that he was HIV-positive, he would be unable to continue to run his business or to stay there. For these reasons, Mark continued to be reluctant to register with a GP and did not wish to divulge his HIV status to the Benefits Agency. In July 1996 Mark discussed his feelings of social isolation with Geraldine Brown, the social worker at the Haemophilia Centre. In his discussions with Mrs Brown, Mark mentioned

that he might like to meet other HIV-positive individuals. Despite Mrs Brown offering to put him in touch with Edinburgh-based support groups or individuals, Mark did not meet other HIV-infected people.<sup>545</sup>

### ***Mark's diagnosis with Progressive Multifocal Leukoencephalopathy***

**5.274** About the beginning of July 1996 Mark suffered a rapid deterioration of his eyesight. He first noticed it when he struggled to read a tape measure at work. He went to an optician and had his eyes tested. He was advised that he needed very weak prescription spectacles but, due to the cost, Mark did not buy them. His eyesight continued to deteriorate and Mark found that he was unable to work. He could not see what he was doing. He had serious problems when riding his motorcycle as he found he could not see where he was going.<sup>546</sup> On 22 July, Mark attended the Haemophilia Centre as he was worried about these symptoms.<sup>547</sup> He was admitted for further investigation. He was found to have minor, superficial widespread lymphadenopathy. His CD4 count was 50 cells/mm<sup>3</sup>, having declined relatively slowly over the preceding 12 years. He was referred to a Consultant Ophthalmologist at the City Hospital in Edinburgh. This doctor confirmed that Mark had a reduction in visual acuity but there was no evidence of retinitis (a disease of the eye that leads to loss of vision and blindness). Mark underwent CT and MRI scans. The results of the MRI scan were suggestive of Progressive Multifocal Leukoencephalopathy (PML).<sup>548</sup> PML is a rare, and usually fatal, disorder of the brain which damages the material that covers and protects nerves in the white matter of the brain. It is a consequence of immune deficiency caused by HIV. There is no known cure for PML. The best therapy is the reversal of the immune-deficient state. In the case of HIV-associated PML, immediate treatment with HAART will benefit most patients.<sup>549</sup>

**5.275** Mark underwent a lumbar puncture and samples were sent for virological studies 'including JC the virus PCR'.<sup>550</sup> He was very uncomfortable after this procedure. 'I think I was a horrible grey colour and in a fair amount of pain'.<sup>551</sup>

**5.276** At the end of September 1996 Mark was told about his diagnosis with PML by two doctors and a nurse.<sup>552</sup> He still had not told anyone that he was HIV-positive and so he had no one with him at this time. He was told that PML was a fatal condition and that it was caused by HIV having detrimentally affected his immune system. He was informed that from the moment when the eyesight starts to fail, the condition gets dramatically worse. He stated that, initially, the doctors were rather vague but they told him that PML was very serious. Mark pressurised them into saying what was going to happen and their response was, 'It's not good, it's not good. You are very ill.'<sup>553</sup> Mark insisted that the doctors explain to him what was likely to happen. He was told that:

[M]y sight would go completely, so I would end up deaf, dumb, blind, incontinent and infirm. And the end result is ... it would only be my heart and lungs that would be working and it would be matter of whichever failed first. All this is likely to occur within three months and you are fairly well advanced already.<sup>554</sup>

<sup>553</sup> Day 32, pages 164–165

<sup>554</sup> Ibid, pages 161–162

**5.277** On hearing this Mark 'wanted it all over'.<sup>555</sup> He stated:

[T]hey had been telling me for years that 'You are very ill, you are dying' .... Well get on with it. You know? I suppose that the anger, the frustration and the rage has faded away. You are now in such a medical mess that to die would have actually been pretty much a relief.<sup>556</sup>

**5.278** Mark was offered treatment with antiretroviral triple therapy but he did not wish to take it due to the side-effects. He decided that he would rather have a good quality of life than extended survival with significant disability.<sup>557</sup>

**5.279** Mark still did not want his parents to know that he had HIV, and that he had been diagnosed with PML. Obviously this caused the medical staff some concern. One of the social workers at the hospital asked Mark how his parents might feel if he died, and he had not warned them about his diagnosis. They both became 'really quite upset' during this discussion.<sup>558</sup>

**5.280** Following his diagnosis with PML Mark was discharged home. On 19 December 1996, Mark attended the Haemophilia Centre. He was found to have expressive dysphasia (difficulty in putting words together to make meaning). The doctors were unsure when this had developed. Their initial concern was that Mark had experienced an intracranial bleed. Mark initially declined treatment with Factor VIII, but relented after about four hours. He was found to have further visual loss in his right eye. The following day Mark had more than 80% recovered from his expressive dysphasia. Due to the sudden deterioration in his condition and his subsequent recovery, Dr Grant, Consultant Neurologist, wondered if Mark had suffered from a seizure. Mark was prescribed Sodium Valproate, an anti-convulsant medication. Mark's CD4 count was still 50 cells/mm<sup>3</sup>. Mark eventually agreed to his parents being informed of his admission to hospital. Professor Ludlam insisted that they were told that he was hepatitis-positive. Mark agreed to Professor Ludlam speaking to them regarding the risk of contact with body fluids, suggesting that they should wear gloves if they were going to come into contact with Mark's body. In view of Mark's increasing disability, this was becoming more likely. Mark's parents were not told of his HIV status, in accordance with Mark's wishes. Mark was discharged from hospital on 23 December.<sup>559</sup>

**5.281** Mark described one of his early seizures:

[I] remember one very horrific one, being woken up late at night, and it was a feeling of being squashed to the floor and I know I lost consciousness. The use of the right-hand side, the arm was then not controllable but I was having difficulty with it. It tended to go off and do its own thing, and in no time at all ... I was losing the use of it and shortly afterwards ... the right leg still worked but not very controllably but the right arm ended up completely floppy and useless.<sup>560</sup>

<sup>559</sup> *Ibid*, pages 167–169; Excerpts from medical records recovered in respect of Mark

<sup>560</sup> Day 32, page 167

**5.282** He also suffered from muscle spasms on the right-hand side, often without warning. His muscles would tighten from the right groin area, his right arm would straighten and then it would twitch uncontrollably. On several occasions he bit his tongue. Mark found these episodes frightening as he often knocked things over. Occasionally he punched himself.<sup>561</sup> He was unable to control the severe seizures, but he discovered that he could control the severity of some of them by bending over, and controlling his breathing.<sup>562</sup>

**5.283** Mark stopped work and, in January 1997, he moved to a town where he was able to receive the support he needed. He was allocated a flat in supported accommodation, in the town. He found this very awkward. At this stage he could still walk although his sight had deteriorated, and he had lost some of the use of the right side of his body. The local social work team provided Mark with regular support and somebody used to visit Mark on Mondays, Wednesdays and Fridays.<sup>563</sup> Initially, Mark found it difficult to accept home help: 'I wanted to do things on my own. I didn't want other people telling me what to do and providing food that I didn't like and didn't want'. Mark also wore an alarm around his neck in case of emergencies.<sup>564</sup>

**5.284** In early February 1997, Mark registered with a GP.<sup>565</sup> One of his support workers persuaded Mark to tell his parents about his diagnosis with HIV and PML. On 19 February Mark invited his parents and his sister to his flat and, after a meal, told them about his condition. Understandably, they were very upset and shocked. Mark gave the doctors at the hospital permission to discuss his condition with his parents and also stated that his parents could make decisions for him, if he was unable to do so. After hearing of Mark's diagnosis his father spoke to the doctors about Mark's condition. Mark continued to attend the Haemophilia Centre for weekly monitoring.<sup>566</sup>

**5.285** Mark's parents became very involved in their son's care: his mother brought him meals and his father took him out for a meal and shopping. He received daily visits from his social worker.<sup>567</sup> At a clinic appointment on 26 February 1997, Mark was noted to be experiencing increasing problems with coordination and loss of power in his right arm and leg. The clinical assistant to Professor Ludlam noted that these problems had become 'considerably worse' since the previous week and that Mark was walking with a marked limp. He was almost unable to use his right arm as his coordination was poor. He had developed aching discomfort in his right shoulder. She considered that Mark was reaching the stage where he was unable to manage on his own at home. Mark told her that he wished to remain in his flat as long as possible, if necessary with 24-hour help.<sup>568</sup>

### *Mark's treatment for HIV*

**5.286** Mark continued to live at his flat with a comprehensive level of support. He often listened to talking books.<sup>569</sup> His condition remained stable. At an appointment on 9 April 1997, Mark discussed antiretroviral treatment for HIV with Professor Ludlam. Mark was given a prescription for Zidovudine and told Professor Ludlam that he would probably start this treatment after discussion with his parents. At his next appointment, on 16 April,

<sup>568</sup> Excerpts from medical records recovered in respect of Mark

<sup>569</sup> Ibid

Mark told the Registrar that he had not started the medication as he was concerned about the side-effects and did not like taking tablets. Mark also told him that his main concern was that people would know about his HIV status if they saw him taking the tablets. The Registrar discussed this with him and, after this appointment, Mark started taking Zidovudine. On 30 April, Mark was also prescribed Didanosine and he started taking this medication in addition to the Zidovudine.<sup>570</sup> In May, Professor Ludlam asked Dr Brettle, a Consultant at the Regional Infectious Diseases Unit, City Hospital in Edinburgh, to assist in the management of the treatment of Mark's HIV.<sup>571</sup> At Dr Brettle's suggestion Mark was prescribed Lamivudine (an NRTI) instead of Didanosine.<sup>572</sup> Mark stated that he suffered stomach upsets as a result of these medications but no more serious side-effects.<sup>573</sup>

**5.287** In May 1997, Mark asked if it was possible for him to obtain an exercise bicycle at his flat. He was aware that the Haemophilia Society provided some bicycles to patients.<sup>574</sup> He was keen to improve his condition by exercise.<sup>575</sup> After starting medication, Mark noticed some improvement in his right arm. He started to get a small amount of movement in the arm.<sup>576</sup> This encouraged him to keep taking medication. At a review appointment at Dr Brettle's clinic on 13 May, Mark's main problems were noted to be poor eye sight, weakness of his right arm, limited mobility, poor memory and an itchy rash. At one point Mark was unable to hold a conversation due to poor memory and poor speech.<sup>577</sup> Mark was prescribed Ketoconazole (an antifungal drug) for his rash. In May 1997 Mark's CD4 count was 40 cells/mm<sup>3</sup> and his viral load was 2000 copies/ml.<sup>578</sup>

**5.288** At an appointment on 5 August 1997, Mark agreed to start taking PCP prophylaxis and was given a supply of Co-trimoxazole.<sup>579</sup> On 25 August Mark was reviewed by Dr Grant, a Consultant Neurologist, and underwent two further MRI scans.<sup>580</sup> These demonstrated findings consistent with arrested PML.<sup>581</sup> On 17 September, at a review appointment at the Haemophilia Centre, Mark was noted to be getting on 'remarkably well'. Mark remained reluctant to start his treatment with Co-trimoxazole and Dr Dennis tried to persuade him to do so. He continued to suffer from a slight tremor in his right arm. He still had considerable difficulty walking, but could manage unaided reasonably well. His vision was no better. Mark was able to do his own washing up and domestic cleaning. Mark's parents continued to visit him regularly.<sup>582</sup>

**5.289** Mark's CD4 cell count from a sample taken in October 1997 was 17 cells/mm<sup>3</sup>. This was similar to the pre-antiretroviral treatment level. His viral load from a sample taken the previous month was 1700 copies/ml. Due to these test results, Mark's antiretroviral treatment was changed, in November 1997, to Didanosine, Stavudine and Nevirapine (an NNRTI). At that time Nevirapine was not yet licensed in the UK. It was available on a named patient basis.<sup>583</sup> Mark was warned that the main side-effect of Nevirapine was a rash. Due to the potential for increased bleeding from protease inhibitors, it was decided

that it was preferable for Mark to avoid this type of drug. Towards the end of 1997 Mark was prescribed Dapsone (to prevent PCP) instead of Co-trimoxazole.<sup>584</sup>

**5.290** In early January 1998, Mark stopped taking Dapsone due to experiencing loose stools.<sup>585</sup> Mark's liver function test results deteriorated as a result of his treatment with Nevirapine. In the middle of that month Mark was contacted by one of the Staff Grade Physicians and he was told to stop taking Nevirapine. On 26 January Mark was admitted to hospital having suffered a possible complex partial seizure. He suffered sudden onset expressive dysphasia. He became increasingly drowsy then slept. When he woke he vomited and developed a headache. His right sided weakness worsened. On admission to hospital Mark was examined and a repeat MRI scan was performed. This showed no evidence of his PML having spread. Mark was discharged from hospital the following day. Mark was prescribed Saquinavir (a protease inhibitor) instead of Nevirapine.<sup>586</sup>

**5.291** The addition of Saquinavir to Mark's HIV treatment had a good effect. In March 1998 Mark's CD4 count had increased to 74 cells/mm<sup>3</sup> and his viral load was lower than 400 copies/ml. In June Mark's dose of Didanosine was stopped as Mark had developed peripheral neuropathy (damage to the peripheral nervous system). The plan was that Mark be prescribed Abacavir (an NNRTI) instead.<sup>587</sup> Unfortunately Mark's liver function tests results remained grossly abnormal, his recent ALT being over 700. It was thought that the cause of this was the antiretroviral medication. Mark was told that it would not be safe for him to take Abacavir but that continuing with just two drugs was sub-optimal therapy. He was told that, from a liver point of view, it would be desirable to stop all medication and monitor his liver function. This ran the risk of Mark's PML progressing. Mark decided to stop the antiretroviral therapy and undergo liver function monitoring. He was told to contact the hospital immediately if there was any change in his neurological state, particularly relating to vision, speech, headaches or weakness.<sup>588</sup>

**5.292** In July 1998 Mark developed a further rash affecting his arms, back and upper thighs. He was prescribed Zirtek (allergy relief medication) and Eumovate ointment (a topical corticosteroid) and referred to the Dermatology Department.<sup>589</sup> By the time Mark saw the dermatologist his rash had improved, although he showed evidence of scalp psoriasis. He was prescribed coal tar shampoo for this.<sup>590</sup>

**5.293** When he was reviewed in September 1998, Mark's liver function tests had reverted to normal, but his HIV viral load had increased to 67,000 copies/ml. His CD4 count had dropped to 55 cells/mm<sup>3</sup>. It was decided that Mark should restart antiretroviral therapy and so he was prescribed Stavudine, Lamivudine (an NRTI) and Efavirenz (an NNRTI).<sup>591</sup>

**5.294** After starting this treatment, Mark's liver function test results deteriorated and then stabilised. He continued to suffer from occasional partial seizures and from muscle spasms mainly in his upper limbs.<sup>592</sup> Towards the end of 1999 Mark was again prescribed Dapsone as PCP prophylaxis. He stopped taking this medication in early 2000 after experiencing numbness of his hands, mood swings and tiredness which he believed were attributable

<sup>592</sup> Ibid

to that medication. He was then prescribed nebulised Pentamidine instead.<sup>593</sup> When he started taking this medication, he received it fortnightly. He suffered from nausea and intermittent diarrhoea. At the beginning of April 2000 he started taking it monthly. This improved the side-effects and he was able to continue taking it.<sup>594</sup>

### ***Mark's symptoms and treatment during the period 2000 to 2006***

**5.295** In May, Mark developed thoracic shingles.<sup>595</sup> In the summer of that year he suffered from a spell of depression and saw Dr Alison Richardson, a Clinical Psychologist. In September he was noted to be feeling a little brighter, had gained weight and was getting out a little more.<sup>596</sup> In addition to his symptoms of HIV and PML, Mark also continued to suffer as a result of bleeds in his right knee. He received treatment for this in the form of intensive physiotherapy, traction and splints.<sup>597</sup>

**5.296** In August 2001, Mark discussed treatment of his Hepatitis C with a doctor working with Dr Brette. His liver function test results remained abnormal. His alphafetoprotein was normal (elevated or rising alphafetoprotein is a marker for the development of liver cancer). It was explained to Mark that his liver disease appeared to be stable; but that the only way to be sure that he was not developing cirrhosis was for him to undergo a liver biopsy. Mark did not want to be treated with Pegylated Interferon and Ribavirin and so he thought there was no point undergoing a laparoscopic liver biopsy. Monitoring of Mark's liver continued by way of blood tests, and regular abdominal ultrasounds.<sup>598</sup>

**5.297** In about March 2002, Mark experienced a further episode of speech disorder, shaking of his upper limbs, altered consciousness and headaches.<sup>599</sup> This was investigated by an EEG and the results were suggestive of temporal lobe seizures. Mark was advised that, if these episodes became more frequent in the future, he might need anticonvulsant therapy but it was not thought necessary at that time.<sup>600</sup> In August 2002 Mark developed mild gynaecomastia (abnormal growth of the male breast tissue) which can be caused by antiretroviral therapy.<sup>601</sup> In the following November he developed aphthous mouth ulcers and was prescribed Corlan pellets.<sup>602</sup>

**5.298** Mark continued to suffer from significant pain and disability as a result of the damage caused to his right knee by repeated bleeds. It was decided that he required a right knee replacement. Due to his HIV status, there was a greater risk of the site of the prosthetic knee becoming infected, and of such an infection being difficult to eradicate. Mark was warned that, in these circumstances, further surgery might be necessary and he could even become septicaemic and have a life-threatening systemic illness. There was also the risk of amputation if such an infection could not be eradicated. Despite these risks Mark was prepared to proceed with this surgery.<sup>603</sup> He was prescribed an additional antiretroviral medication, Tenofovir, in an attempt to reduce his viral load of HIV prior to the surgery.<sup>604</sup> On 29 January 2003 Mark underwent right knee replacement. He made

<sup>603</sup> Ibid

<sup>604</sup> Ibid

good progress following this surgery although his altered gait following the knee surgery caused him to have bleeds in both his ankles. By the April he walked with the aid of a walking stick.<sup>605</sup>

**5.299** Mark developed marked facial lipoatrophy (facial wasting).<sup>606</sup> He was upset about this and, in particular, the idea that it might stigmatise him as being HIV-positive. In April 2004, he was referred to a Consultant Plastic Surgeon to discuss the possibility of treatment by injection with an artificial filling agent.<sup>607</sup> Having consulted with the surgeon and weighed up the risks, which were increased due to his haemophilia, and the possible benefits of treatment, Mark decided against surgery:

I refused. What's the point? I can't see myself in a mirror. Who is going to be looking at you? .... I don't go out, I don't get about. The only people I'm seeing are friends, social workers and colleagues. So what's the point in having more medical procedures, as there is more risk?<sup>608</sup>

**5.300** In July 2004 Mark's antiretroviral treatment was reviewed. At that time he continued to take Stavudine, Lamivudine, Efavirenz and Tenofovir. His CD4 count was 243 cells/mm<sup>3</sup> and his viral load was 537 copies/ml. Resistance tests showed evidence of viral resistance to Lamivudine and Efavirenz so it was not possible to improve Mark's antiretroviral treatment without the introduction of a protease inhibitor or Fuzeon (an HIV fusion inhibitor, administered subcutaneously twice a day). Mark was not keen to change his medication.<sup>609</sup>

**5.301** Mark continued to suffer from partial seizures, including brief 'absences' during which he would stare into space or repeat the word 'yes'.<sup>610</sup> In August 2005, Mark was prescribed Carbamazepine, an anticonvulsant. This was effective in controlling his seizures. Unfortunately, there was a potential interaction between Carbamazepine and Efavirenz and so the Carbamazepine was stopped and he was prescribed Levetiracetam, another anticonvulsant, instead.<sup>611</sup> Mark suffered side-effects from this new drug and so he reduced his dose of that medication himself. In October 2005, he suffered a worsening of his seizures and was admitted to hospital for a night for observation. He was discharged home with the advice to return to his previous dose of Levetiracetam.<sup>612</sup>

### ***Mark's symptoms and treatment during the period 2006 to 2011***

**5.302** In 2005 Mark started attending the clinic of Professor Leen, a Consultant Physician at the Regional Infectious Diseases Unit at the Western General Hospital in Edinburgh. In early 2006, Mark and Professor Leen discussed changing Mark's drug treatment for HIV, and commencing treatment for Hepatitis C. Having discussed the question of treatment with other patients with haemophilia, Mark was reluctant to start treatment for Hepatitis C or to change his treatment for HIV. Professor Leen advised Mark that having his HIV better controlled would be beneficial for his Hepatitis C progression. It was agreed that Mark would consider treatment for Hepatitis C before his next review appointment.<sup>613</sup> In

<sup>610</sup> Ibid

<sup>611</sup> Ibid

<sup>612</sup> Ibid

<sup>613</sup> Ibid

April 2006, Mark told Professor Leen that his main concerns were his increased spasms, his arthritis and his visual impairment. In addition, he told Professor Leen that, in light of the poor response rate of Genotype 1 of Hepatitis C to treatment, he did not want to impair his quality of life by trying treatment for Hepatitis C even for a short period. Mark asked Professor Leen instead to try to improve his quality of life by reducing the number of spasms and monitoring his visual changes. With regard to his treatment for HIV, Mark was aware that on his current treatment, the HIV virus was not fully suppressed. Professor Leen told him that there was ongoing viral replication and that he was likely to acquire new mutations in his HIV which might make future treatment more difficult. Despite this, Mark was not keen to change his HIV treatment. Professor Leen thought that Mark was 'just coping'. He planned to refer Mark back to Dr Grant due to the spasms he was having and to the Consultant Ophthalmologist for advice about his visual problems.<sup>614</sup> Mark subsequently saw Dr Grant in August 2006 who noted that Mark had a postural tremor in his right arm and some unsteadiness on his feet. He thought that Mark looked 'much better than I had seen him previously'.<sup>615</sup> He hoped that Mark would not be troubled further with spasms and neurological pain, and did not arrange any further review.

**5.303** At a review appointment at the Haemophilia Centre on 24 October 2006, Mark complained of bleeding haemorrhoids which had been a problem for a few months. Dr Dennis referred him to Professor Dunlop, Professor of Coloproctology at the Western General Hospital in Edinburgh.<sup>616</sup> At the appointment Mark also expressed some frustration at his inability to undertake everyday tasks, such as shopping. Mark's social work support had been reduced over the years and, at that time: he received three hours per week from a social worker who was unable to drive.<sup>617</sup>

**5.304** In November 2006, after discussions with Professor Leen, Mark agreed to change his treatment for HIV. He was prescribed a new combination of antiretroviral therapy, Etravirine (an NNRTI) and Kaletra (a combination of Lopinavir and Ritonavir, both protease inhibitors) with Truvada. Professor Leen was confident that these drugs would suppress Mark's HIV. Mark was warned about the risk of bleeding as a result of the protease inhibitors.<sup>618</sup> In December that year, Professor Leen noted that Mark seemed 'to have a new lease of life since starting his new medication'.<sup>619</sup> He had had no increased bleeding, and felt much less tired. In January 2007 Mark's HIV viral load was suppressed 'for the first time for a long time if ever'.<sup>620</sup> His CD4 cell count was 153 cells/mm<sup>3</sup> but Professor Leen expected his cell count to rise as his HIV was suppressed.

**5.305** Mark attended Professor Dunlop's clinic for investigation of his rectal bleeding, and initially Professor Dunlop was of the view that the bleeding was caused by an anal fissure. He prescribed Diltiazem cream (a cream used to relax the anal sphincter) for this, but the bleeding continued.<sup>621</sup> On 19 February 2007 Mark was admitted to the Colorectal Unit of the Western General Hospital, after attending the Haemophilia Unit, due to rectal bleeding and pain. The Haemophilia Unit had treated Mark with Factor VIII. Mark did not wish to remain in hospital and so, after being advised about the application of the cream,

<sup>616</sup> Ibid

<sup>617</sup> Ibid

<sup>618</sup> Ibid

<sup>619</sup> Ibid

<sup>620</sup> Ibid

<sup>621</sup> Ibid

was discharged home.<sup>622</sup> A week or so later Mark was admitted to the Colorectal Unit for further investigations. These investigations revealed that Mark had T3 anal squamous cell carcinoma.<sup>623</sup> Squamous cell carcinoma is the second most common cancer of the skin, and T3 means that the tumour is over 5 cm in size. The risk of anal carcinoma is increased in HIV-infected patients.

**5.306** Mark was referred to Dr McLean, a Consultant Clinical Oncologist at the Western General Hospital, for consideration of radiotherapy and chemotherapy. On 13 March, Mark saw Dr Horn, a Consultant Haematologist, at a review appointment. She noted that Mark might require increased prophylactic Factor VIII treatment to cope with his chemotherapy. She also noted that, due to his HIV status and his low CD4 cell count, he might be more susceptible to infection than most patients if he became myelosuppressed (suppression of the bone marrow activity) and neutropenic (abnormally low number of neutrophils, white blood cells) as a result of the chemotherapy treatment. She commented that there would need to be close liaison between Dr McLean, Professor Leen and herself during Mark's cancer treatment. She noted that Mark was continuing to struggle 'considerably' with practical aspects of his life as his partner was unwell, and was staying with him less frequently.<sup>624</sup> Many of his struggles related to his visual impairment, and he found situations like collecting his medication and dealing with his banking and mail difficult. Dr Horn was of the view that he needed support from a worker with experience of working with visually impaired individuals, particularly in light of his impending treatment. She liaised with Professor Leen about this and wrote to the community social worker on Mark's behalf. She advised Mark to cancel a holiday he had booked to Lanzarote on 27 March, in case he experienced rectal bleeding while abroad.

**5.307** On 20 March 2007 Mark underwent a staging MRI and CT scan.<sup>625</sup> In April, when he was 37 years old, Mark started radiotherapy and chemotherapy treatment at the Western General Hospital in Edinburgh. Mark was classed as 'a very high risk patient' to have treatment-related complications, including opportunistic infections, due to his low CD4 cell count. These risks were explained to Mark.<sup>626</sup> He attended the hospital six days a week for this treatment. As a result of the treatment Mark lost all of his body hair, except on his head. During the last week of treatment he was in a great deal of pain. He was prescribed Oramorph (an oral solution containing Morphine) and other painkillers.<sup>627</sup> Mark stated that after the treatment he was given the all clear.<sup>628</sup> After this treatment Mark travelled on the back of a motorcycle around Europe with some friends.<sup>629</sup>

**5.308** On 21 June 2007, four weeks after Mark had finished his radiotherapy and chemotherapy treatment, Dr Horn visited Mark at home. She wrote that she was pleased to see that he had tolerated the treatment very well.<sup>630</sup> She noted that one of Mark's main problems was reduced appetite and episodes of nausea. He had been prescribed Metoclopramide (a medication used to treat nausea) by the Oncology Unit, along with nutritional supplements.

<sup>628</sup> Ibid, page 181

<sup>629</sup> Ibid, page 182

<sup>630</sup> Excerpts from medical records recovered in respect of Mark

**5.309** In October that year, Mark attended an outpatient appointment with Professor Hayes, Professor of Hepatology at the RIE to discuss treatment for Hepatitis C. Professor Hayes conceded, in light of Mark's recent treatment for cancer, that the timing was not perfect for this discussion.<sup>631</sup> Mark proved himself to be very knowledgeable about the likelihood of the success of treatment. Professor Hayes was of the view that Mark was possibly at either a pre-cirrhotic or early cirrhotic stage, characterised by a slightly reduced platelet count, and a higher serum hyaluronic acid concentration.<sup>632</sup> As Mark had never undergone a liver biopsy, it was difficult to be more definite about whether he had cirrhosis or not.<sup>633</sup> He suggested that Mark continue with surveillance for hepatocellular carcinoma with six-monthly alphafetoprotein checks. He noted that Mark had previously had an endoscopy which had showed one column of grade two varices. He was being treated with Propranolol (a medicine used to treat a number of conditions, including varices).

**5.310** On 8 January 2008, Mark attended an appointment at the Haemophilia Centre. At the previous appointment in December 2007 a small lymph node was palpable in Mark's neck. When he was re-examined at his appointment in January there was no longer lymphadenopathy palpable in his neck. Dr Horn noted that Mark was under some stress due to problems with neighbours; his sleeping pattern was abnormal, and he was experiencing waking early. She also noted that Mark was still struggling with his social circumstances. A Consultant Ophthalmologist had offered Mark an appointment at the Vision Support Centre. Unfortunately this appointment did not take place as he was diagnosed with anal cancer around the same time and his oncology appointment took precedence. Dr Horn planned to write to ask for the appointment to be rescheduled.<sup>634</sup>

**5.311** About a year after Mark's diagnosis with anal cancer, he attended a review appointment with Professor Dunlop. Professor Dunlop found a lump and, after further investigation including surgery, Mark was advised that the anal cancer had recurred. He was told that the only treatment option was abdominoperineal resection (removal of the anus, the rectum and part of the sigmoid colon) with a permanent colostomy. Mark underwent this procedure on 13 August 2008. While he was an in-patient, an occupational health worker came to speak to him about the support he would need at home. The worker put on a mask, gown and gloves and stood at the far side of the room to speak to him.<sup>635</sup> Mark recovered very well from the surgery.<sup>636</sup> There was a concern that, due to Mark having undergone radiotherapy so recently, the wound would not heal properly and might remain open. However it healed well and Mark described the scars as 'impressive'.<sup>637</sup> There was concern about how Mark would cope with a colostomy in view of his visual impairment, but in fact he managed 'surprisingly well'.<sup>638</sup> In October 2008, Dr McLean noted that Mark 'really is a remarkable man, given all his adversities .... He really is quite inspirational'.<sup>639</sup>

<sup>637</sup> Day 32, pages 181–182; Excerpts from medical records recovered in respect of Mark

<sup>638</sup> Day 32, page 181

<sup>639</sup> Excerpts from medical records recovered in respect of Mark

**5.312** Mark has continued to experience muscle spasms and episodes of tremor, particularly affecting his right side. This has exacerbated the pain he has experienced due to bleeds, and has affected his ability to inject himself with Factor VIII. In June 2010, Mark was referred back to Dr Grant for advice about the tremor and absence seizures.<sup>640</sup> Dr Grant noted that these worsened when Mark was anxious, and he suggested that Mark's doses of Propranolol and Levetiracetam be increased and, if that did not improve his symptoms, then he be prescribed Diazepam.<sup>641</sup> In the October, Mark's CD4 count was 219 cells/mm<sup>3</sup> and his viral load was lower than 40 copies/ml.<sup>642</sup>

**5.313** In December 2010, Mark complained of poor appetite and nausea. He wondered if there might be a psychological component to these symptoms as he associated eating with his colostomy bag filling up.<sup>643</sup> These symptoms subsequently improved.

**5.314** With regard to treatment for Hepatitis C, Mark has continued to have regular discussions about this with Professor Leen and, occasionally, at his Haemophilia Clinic appointments, with Professor Hayes about this. A liver ultrasound in 2010 was 'satisfactory', with no evidence of any focal lesion.<sup>644</sup> Mark is aware of the new treatments which have been recently licensed, and are likely to benefit, in particular, those who have Genotype 1 of the virus.<sup>645</sup> It is unclear when Mark will be eligible for treatment with these new drugs.<sup>646</sup>

#### *Specific impacts of Mark's infection with HIV*

**5.315** It is apparent that the impact of all Mark's symptoms and disabilities has made, and will continue to make, life extraordinarily difficult for him. He is registered blind, and although he does have some awareness of things moving on his left-hand side, he is unable to read or recognise people.<sup>647</sup> He has advanced arthritis in his knees, both ankles and both elbows as a result of bleeds. Sometimes he is wheelchair bound when a bleed occurs. Otherwise he walks with the support of a stick or crutches.<sup>648</sup> Mark has regained strength in his right arm but has little coordination of it.<sup>649</sup>

**5.316** A very significant impact of Mark's symptoms of HIV in combination with his haemophilia is that Mark has needed, and will continue to need, support with day-to-day living. It was apparent from Mark's evidence that he has strived for his independence. He stated:

I have tried to live a lot of my life very independent and the lack of sight very much takes that away. I'm relying on other people for everything from shopping to transport and that has got to be one of the hardest things for me to deal with, you know, to take that deep breath and allow other people.<sup>650</sup>

<sup>640</sup> Ibid

<sup>641</sup> Ibid

<sup>642</sup> Ibid

<sup>643</sup> Ibid

<sup>644</sup> Ibid

<sup>645</sup> These new treatments are discussed in more detail in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.115.

<sup>646</sup> Excerpts from medical records recovered in respect of Mark

<sup>647</sup> Day 32, page 95

<sup>648</sup> Excerpts from medical records recovered in respect of Mark

<sup>649</sup> Mark's Witness Statement

<sup>650</sup> Day 32, page 187

**5.317** In a letter to the City of Edinburgh, Health and Social Care Department dated 18 November 2009, Dr Horn wrote:

[Mark] has coped extremely well over the years with the many difficulties that have faced him. Although he has support from a number of agencies, this is not proving sufficient to meet his very unique needs at present and there is also a lack of continuity of care for [Mark], which is having a major impact on his ability to cope with life.

He is also becoming increasingly socially isolated as a result of difficulties taking part, without support, in the activities that he enjoys.<sup>651</sup>

**5.318** Giving some insight into the type of support which Mark needs, she wrote:

[T]here seems to be a lack of continuity and there have been several instances of [Mark] not realising the timing of important appointments and missing them because he cannot read his appointment cards/letters. He is also struggling with his medication, which is very complex and although he has managed this very well over the years he feels and I agree, that he is requiring more help with this. The counsellors who have been provided to give him psychological support are increasingly inappropriately involved in doing practical tasks for him. He has difficulty with shopping and sometimes difficulty with meal preparation. His condition means that he is vulnerable to losing weight if his nutritional in-take is inadequate and he is currently having ready meals or snacks prepared for him intermittently when possible. He has lost his confidence in going out alone and is struggling with issues such as his banking. The district nurses provide support for his stoma and he is able to do some of the stoma care himself. However there are aspects of his stoma care that he cannot manage on his own and he is currently sometimes relying on his parents for this.<sup>652</sup>

**5.319** Like others needing support at home, Mark has had to cope with changes in the care he receives, and has had to argue for more support. This has taken its toll on Mark. In 2009, he was seen by a Consultant Clinical Psychologist from the Edinburgh Cancer Centre at the Western General Hospital. This psychologist believed that the low mood that Mark was experiencing at the time was 'directly related to his frustrations and anger regarding the level of social support and nursing care that he is receiving'.<sup>653</sup> She wrote:

I have the impression that he has tried on many occasions in the past to be able to effect some change, but has had little success. [Mark] has always been a man who has prided himself with being effective and competent and it is particularly difficult for him to manage his multiple health conditions while having less security in the quality of the care that is being offered to him. Although I would describe [Mark] as experiencing a moderate level of depression at present, I am concerned that his low mood may well escalate should these difficulties in his care not be resolved.<sup>654</sup>

---

<sup>651</sup> Excerpts from medical records recovered in respect of Mark

<sup>652</sup> Ibid

<sup>653</sup> Ibid

<sup>654</sup> Ibid

**5.320** Now Mark has home-help support every day of the week which, he stated, 'certainly makes a difference'. He stated that he has 'a fair degree of determination to stay in [his] own house'.<sup>655</sup>

**5.321** When asked how he spends his time, Mark stated that he has a talking computer. He has had parts of his home and garden adapted so that he is able to move around outside and go upstairs. One issue for him is that he needs to know where everything is so that he can move around safely. For example, if a home help puts a sharp knife in a different place, Mark is unable to see it and may injure himself as a result.<sup>656</sup>

**5.322** Mark owns his home and has a mortgage for this arranged through the MacFarlane Trust. He has never applied for life insurance and has no pension. Mark obtained travel insurance after his chemotherapy and radiotherapy treatment. He stated that it was more expensive as he had undergone a serious medical procedure within 12 months. Mark has received both Skipton Fund payments and recently he has applied for the increased payment.<sup>657</sup>

**5.323** Mark has some feelings of regret that he did not tell his parents sooner that he was HIV-positive: 'I feel I have let them down to some degree'.<sup>658</sup> He stated that it was awkward not telling them his diagnosis at the time. Like Mark, his father likes motorcycles too. Mark used to ride his motorcycle past their house but he did not stop and say hello because 'there was the possibility of conversation. You know, if he had asked me directly, I wouldn't have been able to deny it'.<sup>659</sup> He stated, on the other hand:

I think in the scheme of things it has probably helped my parents to some degree because they didn't know. I know the stress and concern would have been greatly increased over the years. Again, I think, if I had told them, they would have been very enthusiastic for me to start taking medication or antiretrovirals before I actually did, which in the scheme of things may not have been beneficial.<sup>660</sup>

**5.324** Mark stated, 'My parents and sister have been a fantastic help to me'.<sup>661</sup>

**5.325** When asked about the personal impact of his infection with HIV, Mark stated:

I suppose the thing that I remember is how my world was smashed into a million pieces from one sentence, when Ludlam told me what the situation was;.... So again I suppose it's the same situation. I mean, I'm in my 40s. I did not expect to get this far. Again whether I have helped myself by refusing medication and letting my body get on with things, it's difficult to say. The biggest problem I have at the moment again is my sight ... But it has – very much brought out who my proper friends are and who is on my side.<sup>662</sup>

## CHAPTER 6

### AN EXAMINATION OF THE EFFECTS OF INFECTION WITH HEPATITIS C ON THE PATIENTS AND THEIR FAMILIES, INCLUDING TREATMENT

#### Introduction

**6.1** This chapter deals specifically with the effects of infection with Hepatitis C, on those who were infected by blood and blood products, and on the families of infected persons.

#### Hearings of evidence

**6.2** The hearings of evidence on this topic took place on 8, 9, 13, 14 and 15 December 2011 and on 10 January 2012. The following patients or relative witnesses<sup>1</sup> gave evidence to the Inquiry in respect of this topic:

1. Stephen
2. Bridie
3. Colin
4. Gordon
5. Laura
6. Anne
7. Alex

**6.3** Their evidence is narrated in this chapter. Another witness, Christine, who gave evidence about her son's infection with HIV also spoke about her own infection with Hepatitis C from blood products. Her evidence, insofar as it is relevant to this topic, is also included in this chapter.

**6.4** In addition, both Professor Howard Thomas and Professor Peter Hayes (Professor of Hepatology in the Liver Unit, Royal Infirmary of Edinburgh (RIE) with Honorary Consultant Physician status with Lothian Health Board), provided the Inquiry with a clinical view on the effects of infection with Hepatitis C on patients and their families. Their evidence is referred to, where appropriate, throughout this chapter.

#### Stephen

**6.5** Stephen was 44 years old when he gave evidence. He is married and has a daughter. He lives in the north of Scotland and works in the financial sector.<sup>2</sup> Stephen suffered from Haemophilia A and acquired both the HIV and Hepatitis C viruses from blood products.<sup>3</sup>

#### *Stephen's diagnosis with and treatment for Haemophilia A*

**6.6** In 1968 when he was 11 months old Stephen was diagnosed with severe Haemophilia A, having a clotting factor of less than 1%. His maternal great grandfather and a cousin also had haemophilia.<sup>4</sup> He was treated as a child at the local children's hospital and, from about the age of 13 or 14 years, at the regional hospital.<sup>5</sup>

---

<sup>1</sup> As detailed in the Appendix, in order to preserve their anonymity, each witness was given a pseudonym

<sup>2</sup> Day 75, pages 2–3 and page 56

<sup>3</sup> Ibid, page 3; Stephen's Witness Statement

<sup>4</sup> Day 75, pages 3–5

<sup>5</sup> Ibid, pages 5 and 10

**6.7** The first haemophilia treatment Stephen received was in 1968 when Russell's viper venom was applied to stop bleeding gums.<sup>6</sup> Stephen's next haemophilia treatment was in 1974 when he was treated with cryoprecipitate before and after dental extractions. Thereafter he continued to be treated with cryoprecipitate. The severity of his haemophilia meant that Stephen required treatment frequently: in 1974, on 13 separate occasions.<sup>7</sup>

**6.8** Stephen's mother recorded every treatment he received in a diary. On 2 February 1976 a diary entry records that Stephen received 'New stuff, not cryo ...'.<sup>8</sup> It seems likely that this is a record of Stephen's first treatment with Factor VIII concentrate. The diary then records that, on 24 April 1976, Stephen was admitted to hospital with 'jaundice, serum hepatitis ... discovered eyes yellow'.<sup>9</sup> He was treated with rest in isolation and remained in hospital for 32 days. This acute attack of hepatitis may have been acute Hepatitis B (screening of blood for HBV was still not completely reliable in early 1976) or conceivably an acute attack of Hepatitis C (NANB Hepatitis was barely recognised in 1976). Thereafter Stephen was treated variously with cryoprecipitate or Factor VIII until the early 1980s when his treatment became solely Factor VIII.<sup>10</sup>

**6.9** By early 1982, Stephen required treatment for his haemophilia approximately every third day. Each treatment involved a 64 mile round trip to the hospital. Stephen's mother usually took him for treatment as his father worked away from home a week at a time. Stephen missed school every time he attended for treatment but did not allow this to impact on his school work.<sup>11</sup> To his credit he left school having passed five higher and nine 'O' grade exams.<sup>12</sup> Contrary to the advice of his haemophilia consultant, he played golf, football and squash.<sup>13</sup> After leaving school, Stephen started working at a bank and, in his spare time, studied for a degree in management accounting. Having obtained his degree, he subsequently became a member of the Chartered Institute of Bankers and was awarded a Fellowship of the Institute.<sup>14</sup>

### *Stephen's diagnosis with HIV*

**6.10** In about February 1986, when Stephen was 18 years old, his then haemophilia consultant told him that he was HIV-positive.<sup>15</sup> In a letter to Stephen's GP dated 27 February 1986, the consultant confirmed that Stephen's HTLV-III antibody status was positive and wrote:

I discussed the situation and some of the implications of this positive test with him when I told him the result. The immediate implication is simply that he has met this virus at some point in the past and has made antibodies to it – the fact that this test is positive does not mean that he has got AIDS. We know that a small but uncertain proportion of people with this positive antibody do go on to develop AIDS in the future, but we cannot identify those who will.<sup>16</sup>

<sup>14</sup> Ibid, page 12

<sup>15</sup> Ibid, page 11

<sup>16</sup> Ibid, page 13; Excerpts from the medical records recovered in respect of Stephen

**6.11** Stephen was unsure if the doctor told him all that is written in this letter but he remembers it being emphasised that although Stephen was HIV-positive, he did not have AIDS. The doctor warned Stephen of the risk of sexual transmission of the virus and of the care he needed to take discarding needles and if he were to cut himself.<sup>17</sup>

**6.12** Stephen knew what HIV was when he was told about his diagnosis. At that time there were 'hard hitting' advertisements on the television about AIDS featuring a falling tombstone.<sup>18</sup> Notwithstanding this, Stephen did not worry about his diagnosis. Stephen stated that he was not a person who worried: 'you don't worry about much in life when you are that age .... I have never let it worry me. I have got it and I have to deal with it. It's just as simple as that'.<sup>19</sup> Stephen immediately told his parents about his diagnosis but he cannot remember how they reacted to the news. He suspects that his parents may have hidden their reaction from him. He did not tell his sisters or anyone else at that time.<sup>20</sup>

### *Stephen's treatment for HIV*

**6.13** Stephen continued to attend the hospital for monitoring and blood tests every three months.<sup>21</sup> He commenced taking Zidovudine medication in August 1992.<sup>22</sup> He suffered no side-effects from it and it had no impact on his day to day life.<sup>23</sup> As Stephen's cousin's husband was the local pharmacist, arrangements were made for Stephen to obtain the medication from the pharmacy in a nearby town instead so that he could keep his diagnosis a secret.<sup>24</sup>

**6.14** Stephen's medical records show that triple therapy treatment for HIV was discussed with him in June 1998 but Stephen remained on AZT. Stephen accepted advice and recommendations of his doctors in relation to treatment.<sup>25</sup> In June 1998, Stephen was noted to have swollen parotid glands (salivary glands which lie in front of and just below each ear), a symptom of HIV.<sup>26</sup> In 2002 Stephen developed some degree of facial atrophy (wasting of fat from the face), a known side effect of AZT treatment.<sup>27</sup> Other than swollen glands, Stephen has had few symptoms of HIV and his viral load has remained undetectable.<sup>28</sup>

### *Specific impacts of Stephen's infection with HIV*

**6.15** Stephen's infection with HIV had an impact on relationships. In 1987 Stephen was in a relationship with a girl. Although he knew that he was not going to marry her, he felt 'forced to ... put her in front of the doctor to explain things ...'.<sup>29</sup> Stephen asked the doctor not to tell her that he was definitely HIV-positive. In June 1987 Stephen and his girlfriend met with the consultant and had 'a prolonged and wide-ranging discussion of the implications of HIV and haemophilia'.<sup>30</sup> In a letter following that meeting the consultant recorded:

---

<sup>17</sup> Day 75, pages 14 and 17

<sup>21</sup> Ibid, pages 29 and 35

<sup>22</sup> Ibid, page 28; Excerpts from the medical records recovered in respect of Stephen; Zidovudine is a type of antiretroviral drug. It was the first drug approved for patients with HIV.

<sup>23</sup> Day 75, page 29

<sup>24</sup> Ibid, pages 29–30; Excerpts from the medical records recovered in respect of Stephen

<sup>25</sup> Day 75, page 40; Excerpts from the medical records recovered in respect of Stephen

<sup>26</sup> Day 75, page 42

<sup>27</sup> Ibid, page 44

<sup>28</sup> Ibid, page 17

<sup>29</sup> Ibid, pages 18–21

<sup>30</sup> Ibid, page 19; Excerpts from the medical records recovered in respect of Stephen

We discussed the following areas:

1. The fact that all severe haemophiliac patients in Scotland should be regarded as having met the HIV virus at some stage in the past regardless of any blood test ....
2. The result of 1, is that it is sensible to regard all severe haemophiliac patients as potentially infective and of course the commonest means of transmission of the virus is by sexual activity. The most effective means of preventing such transmission is the meticulous and invariable use of sheath.
3. As a result of 1 and 2, it is clearly sensible for the partners of haemophiliac men to plan not to conceive in the immediate future ....
4. When asked about [Stephen's] future I gave what had to be a guarded reply saying that we could not guarantee that he would not develop AIDS in the future although he appears in very good health at present. We would of course be keeping a close eye on his well-being.

The consultant further recorded that he thought that the information he had given was more than enough for them to digest. He asked them to go away and think about the situation and to return to see him any time they wished so that any misconceptions they would have could be clarified and any new questions answered.<sup>31</sup>

**6.16** A further impact of Stephen's diagnosis with HIV was in relation to travel. In 1992 Stephen married.<sup>32</sup> In order that he and his wife could travel to the USA for their honeymoon, they had to obtain the help of his then consultant. Unknown to Stephen at the time, she wrote to a local travel agent for advice about this. This travel agent was one of Stephen's clients and Stephen says that he was quite annoyed when he subsequently discovered the consultant had written to that company, although she had not specified Stephen's name. The letter was completely anonymous and could not have been understood to refer to Stephen. The travel agent, who had helped in dealing with the travel problems of other patients, in turn asked the US Embassy in London for advice. This advice in November 1991 was that aliens who were HIV-positive were ineligible for a visa under US law and therefore were ineligible to travel under the visa waiver pilot programme. This ineligibility could be waived in certain circumstances, including if the stay was 30 days or fewer and only for visits which involved public benefit outweighing public risk. Public benefit included family visits, medical treatment and business travel. A letter from a physician was required to support an application to waive the ineligibility, addressing the alien's current state of health, the risk to US public health and the risk of spread of infection.<sup>33</sup> The consultant wrote in support of Stephen's trip to the USA and Stephen was granted the necessary waiver. With regard to the requirement for travel insurance, Stephen and his wife eventually found a firm which specialised in haemophilia, HIV and Hepatitis C related illnesses, but obviously it was not easy for them. When trying to obtain insurance, Stephen was uncomfortable disclosing to the insurance agent that he was HIV-positive and later Hepatitis C-positive, 'But it was over the phone, so they wouldn't have known me supposing I walked past them today .....'<sup>34</sup>

---

<sup>31</sup> Excerpts from the medical records recovered in respect of Stephen

<sup>32</sup> Day 75, page 22

<sup>33</sup> Ibid, pages 24–25; Excerpts from the medical records recovered in respect of Stephen

<sup>34</sup> Day 75, page 28

**6.17** Since his honeymoon Stephen has travelled a number of times to the USA. Now he no longer needs to apply for a visa waiver but still he is questioned at immigration. After 9/11 Stephen had to attend in person at the American Embassy in Belfast to obtain the necessary visa, which involved the time and cost of travelling to Belfast. On a number of occasions, while on the aeroplane to the USA, Stephen has been required to fill out a different coloured immigration form to the majority of other passengers. At one time one of the questions on this form was, 'Are you a Nazi, a terrorist or HIV-positive?'<sup>35</sup> Stephen found these forms degrading. He considered they singled him out as different from other passengers.<sup>36</sup>

### *Stephen's diagnosis with Hepatitis C*

**6.18** It is unclear when Stephen first became aware of the fact that he had acquired Hepatitis C. There is an inconsistency between his recollection of finding out and what is stated in his medical records.

**6.19** Stephen can clearly remember being told he was HIV-positive, but he cannot remember ever having been told that he had acquired Hepatitis C: 'I don't remember the smack in the face that I remember with HIV'.<sup>37</sup> Stephen stated that having Hepatitis C was something that he became aware of.<sup>38</sup> He thinks that he first knew he had Hepatitis C in the late 1990s or the early 2000s. He stated that, had he known that he had Hepatitis C, he would have told his wife before they married in 1992 (he told her at this time he had HIV) or when she became pregnant in 1996.<sup>39</sup> Furthermore, when Stephen's wife became pregnant he and his wife asked that she be tested for HIV. He stated that had he known he had Hepatitis C they would have asked for her to be tested for this too.<sup>40</sup> In fact, on 26 September 1996 Stephen's wife was tested for both HIV and Hepatitis C, the results of both these tests being negative.<sup>41</sup> Stephen and his wife said they were unaware that she was tested for Hepatitis C until they saw the result of the test in his medical records in 2008.<sup>42</sup>

**6.20** In contrast to Stephen's recollection, the first mention in Stephen's medical records of the fact that he had acquired the Hepatitis C virus is a letter from the consultant to Stephen's GP dated 8 January 1992. This letter recorded that various viral investigations had shown that Stephen had antibodies to Hepatitis C.<sup>43</sup> Nothing in this letter suggests that Stephen was informed of this.

**6.21** The next mention of Hepatitis C in Stephen's medical records is a handwritten note on the bottom of a letter from the haemophilia consultant addressed 'To whom it may concern' dated 27 April 1995. This note appears to have been written at a subsequent clinic appointment on 8 June 1995 and states '[K]nows about Hep C. Wife had Hep A three years ago'.<sup>44</sup> A letter dated 9 June 1995 about this clinic appointment to Stephen's GP records, 'He is hepatitis C positive and does not want anything further done about this. He is, of course, HIV positive. His wife had hepatitis A 3 years ago but I have offered

<sup>44</sup> Day 75, page 33; Excerpts from the medical records recovered in respect of Stephen

that we check her out if he wants to'.<sup>45</sup> Stephen cannot remember this consultant ever speaking to him about Hepatitis C.<sup>46</sup> She ceased being Stephen's treating consultant in about March 1996 when a different consultant haematologist was appointed.

**6.22** A report from the Department of Medical Microbiology dated 28 July 1995 on a blood specimen obtained on 8 June 1995 recorded that Stephen was HCV PCR positive and that he had Genotype 3a of the virus.<sup>47</sup> On 29 August 1995 the consultant wrote to Stephen's GP advising him of these results and stating that Stephen would be suitable for Interferon.<sup>48</sup> At this time Stephen was undergoing liver function tests. Stephen stated that he used to have blood tests every three months which he thought were to check his CD4 ratio with regard to his HIV status. He accepted that 'liver function test' might have been mentioned to him but stated that he would not have associated that with Hepatitis C.<sup>49</sup> An ultrasound on 9 February 1996 revealed that Stephen's liver was enlarged, measuring over 17 centimetres in diameter, there were several gallstones within his gall bladder and his spleen was enlarged.<sup>50</sup> Stephen has no recollection of the ultrasound or of these results.<sup>51</sup>

**6.23** In a letter to Stephen's GP, dated 11 March 1996, his then consultant haematologist stated that at a clinic appointment the same day he discussed with Stephen 'the implications of HCV infection, our plans for its surveillance and the therapeutic options that are available for its treatment'. This letter records the doctor's impression that Stephen did not wish to have treatment with alpha Interferon 'in view of the side-effects and the very low rate of success for clearance of the virus and normalisation of ALT in HIV-infected haemophiliacs'.<sup>52</sup> Once again Stephen has no recollection of this. This letter also records that Stephen agreed to undergo an endoscopy and that the doctor planned to try to arrange this for May 1996. Stephen pointed out that he did not undergo an endoscopy until 2004 and this was borne out by his medical records.<sup>53</sup>

### *Stephen's discussions with doctors about treatment for Hepatitis C*

**6.24** Stephen remembers a discussion in the late 1990s/early 2000s with his consultant during which he was told that he should be more concerned about his infection with Hepatitis C than with HIV.<sup>54</sup> At that time, Stephen had no idea that Hepatitis C could cause him more harm than HIV.<sup>55</sup>

**6.25** The timing of this discussion coincides with the time when the consultant, like other clinicians, started to understand more about the likely consequences of patients' infection with Hepatitis C. Having initially considered it to be a fairly benign condition, clinicians came to realise that a large number of patients would develop major complications as a result of the virus, including cirrhosis and its complications.<sup>56</sup> This realisation impacted on clinicians' views about when to treat a patient, which also evolved over the years.<sup>57</sup> Prior to

<sup>53</sup> Day 75, page 37

<sup>54</sup> Stephen's Witness Statement

<sup>55</sup> Day 75, page 44

<sup>56</sup> Professor Hayes – Day 78, page 80

<sup>57</sup> Report from Professor Hayes [PEN.018.0240] at 0245

2004, NICE<sup>58</sup> recommended that only those patients with severe disease should be treated and that the assessment of the severity of the disease should be based on a liver biopsy.<sup>59</sup> Due to the additional risks of a liver biopsy for those patients with haemophilia, they were exempted from this requirement.<sup>60</sup> In April 2004, at a Consensus Conference on Hepatitis C in Edinburgh, it was decided that a liver biopsy was no longer essential to the selection of patients for therapy. Then, in 2005, the Scottish Executive produced a 'Hepatitis C Action Plan for Scotland'.<sup>61</sup> This highlighted the importance of treating as many people as possible rather than tailoring treatment to those persons clinicians believed needed it most.<sup>62</sup>

**6.26** At a clinic appointment on 20 March 2000, Stephen and his consultant discussed treatment with Interferon and Ribavirin.<sup>63</sup> At this time the doctor was aware that being male and co-infected with HIV were major risk factors in the progression of Hepatitis C.<sup>64</sup> It was noted that Stephen's HIV infection was progressing extremely slowly with no significant morbidity and no significant fall in his CD4 count.<sup>65</sup> The doctor thought that there was no immediate urgency to start treatment. It was decided to await the outcome of further studies on the use of combination therapy for Hepatitis C in the context of HIV therapy, before deciding what treatment to pursue for Hepatitis C.

**6.27** In May 2002 Stephen had a further discussion with his consultant about treatment for Hepatitis C. The doctor told him that there was data available which showed that HIV-infected patients with high CD4 counts could safely be treated with alpha Interferon and Ribavirin, along with anti-HIV therapy, without significant problems. He also told him that success rates of around 40% for viral clearance using Pegylated Interferon and Ribavirin had been reported.<sup>66</sup> It was suggested to Stephen that one option which would inform the debate about treatment was to consider the possibility of a liver biopsy in order to ascertain the histological appearances of the liver. Stephen does not remember what he thought about a liver biopsy at this time.<sup>67</sup>

**6.28** Stephen tried to live life as normally as possible despite his diagnoses, but obviously they preyed on his mind to a certain extent. In November 2002, some fairly innocuous symptoms caused Stephen to become wrongly convinced that he had developed cancer.<sup>68</sup>

**6.29** At a clinic appointment on 17 February 2003 treatment for Hepatitis C, and the side-effects and expected outcomes of treatment were discussed once again with Stephen. Stephen did not wish to embark on the treatment over the summer holidays but indicated that he was happy to consider it in the autumn of that year.<sup>69</sup> In May 2003 Stephen developed high blood pressure. An ECG suggested that he might have developed left ventricular hypertrophy (thickening of the muscle of the left ventricle of the heart) but an echocardiogram did not confirm this.<sup>70</sup>

### *Stephen's treatment for Hepatitis C*

**6.30** Towards the end of 2003, Stephen decided that he wished to start treatment with Interferon and Ribavirin in an attempt to treat or at least slow down the progression of the virus.<sup>71</sup> In April 2004, Stephen attended an appointment with a Consultant Physician/Gastroenterologist and a Hepatology Clinical Nurse Specialist to discuss this. It was noted at this appointment that Stephen's liver enzyme levels had been deranged for some time and that he looked mildly jaundiced. He had a raised level of bilirubin (a sign of damage to the liver) and an alpha-fetoprotein of 14, the latter being noted as indicative of hepatocellular carcinoma but more likely to reflect cirrhosis against the background of Hepatitis C.<sup>72</sup>

**6.31** Stephen was told that there was increasing evidence that Hepatitis C co-infection should be treated in patients with HIV and that Hepatitis C was now the major cause of death among co-infected patients. He was also told that he had Genotype 3a of the virus and although this was one of the more favourable genotypes to treat, if he had cirrhosis as well as HIV infection then his chances of viral eradication would be much lower. He was advised that it was likely he would require 12 months of antiviral therapy with significant side-effects and around a 25% chance of being intolerant of the treatment.<sup>73</sup> The Consultant Physician told Stephen that if he did have cirrhosis then he would not tolerate the treatment and it may cause him to have hepatic decompensation. Stephen was provided with some literature on the treatment and given some web sources of information on it.<sup>74</sup> It was agreed that Stephen would undergo an ultrasound of his liver to exclude hepatocellular carcinoma (cancer of the liver) and an endoscopy check for oesophageal varices (varicose veins in the stomach and gullet). Stephen found the prospect of starting treatment 'a bit daunting but [he] knew it had to get done'.<sup>75</sup>

**6.32** In June 2004 Stephen underwent an endoscopy.<sup>76</sup> He did not know what an endoscopy was and so underwent it without an anaesthetic, something he will not repeat.<sup>77</sup> The endoscopy disclosed that Stephen had four varices.<sup>78</sup> The consultant would have prescribed Propranolol for Stephen to treat the varices but decided against it due to Stephen having suffered a life-threatening asthma attack in 1993.<sup>79</sup> An abdominal ultrasound scan in July 2004 revealed that Stephen had moderate hepatosplenomegaly (enlargement of the liver and the spleen). His spleen measured 20cm at its widest. His liver showed evidence of cirrhosis.<sup>80</sup>

**6.33** On 31 March 2005 Stephen started antiviral therapy for Hepatitis C.

**6.34** Treatment consisted of Pegylated Interferon Alpha 2b 150 mcg by subcutaneous injection once per week and Ribavirin capsules, 1200 mg daily divided into doses. It was planned that Stephen would receive 48 weeks of treatment with his Hepatitis C PCR response being checked at 24 weeks and a decision on whether to continue with

<sup>80</sup> Day 75, page 54

the treatment for a further six months would be made at that time.<sup>81</sup> This was in line with 'stopping rules' which became more refined over the years and were eventually documented in the SIGN (Scottish Intercollegiate Guidelines Network) guidelines on the management of Hepatitis C, dated December 2006.<sup>82</sup> These rules defined when a person should stop treatment. For example, if a person with Genotype 1 of the virus failed to achieve an early viral response after 12 weeks of treatment then it was known that this person would be extremely unlikely to be cured and would simply suffer the complications and side-effects of the treatment.<sup>83</sup>

**6.35** The night he started his treatment, Stephen sat with his wife before giving himself the first injection of Interferon, wondering what effect it would have on him and how immediate such an effect would be.<sup>84</sup> In the event, initially Stephen did not suffer any severe side-effects and he found the treatment 'okay'.<sup>85</sup> In June 2005 the amount of Interferon Stephen was prescribed was reduced to 90 mcg due to a fall in his platelet count and neutrophils.<sup>86</sup> These are known side-effects of the treatment. A detailed summary of the known side-effects of Interferon and Ribavirin is given in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.107. When his PCR level was tested after six months of treatment, the result showed that Stephen had cleared the virus. Stephen thought that this was good and that it was worth carrying on with the treatment. He understood that it was hoped that the treatment would clear the Hepatitis C virus, but that he may still eventually need a liver transplant.<sup>87</sup> Unfortunately, Stephen's clearance of the virus proved to be temporary.

**6.36** In about mid-October 2005, Stephen began to feel generally unwell and his condition changed markedly. At this time Stephen was working full-time in a business development role at the bank, which involved him 'being out and about a lot'.<sup>88</sup> He usually worked 12 to 14 hours a day. Stephen felt tired and unable to work his usual working day. He was unable to do tasks which he normally took for granted. He would read things and not understand what he was reading. He found that he forgot what he had already read. His employers had been unaware of his diagnosis with Hepatitis C but Stephen felt that, due to these symptoms, the time had come to disclose this to them and ask them for their support. On hearing of his diagnosis, Stephen's employers were 'absolutely fantastic'.<sup>89</sup> He was subsequently absent from work for 22 months and his employers paid him his full salary for this period.

**6.37** Stephen experienced the following symptoms during the latter stages of his treatment which may have been due either to the side-effects of the treatment or to his liver disease: low levels of concentration, no energy, severe nose bleeds, loss of appetite, thinning of his hair, severe muscle cramps, including one occasion when he had cramp 'in just about every single joint in [his] body at the same time', insomnia, nausea and vomiting.<sup>90</sup>

<sup>88</sup> Day 75, page 59

<sup>89</sup> Ibid, pages 59–60

<sup>90</sup> Ibid, page 60

**6.38** On 3 October 2005 Stephen was prescribed medication, namely GCSF 105 mcg three times weekly by subcutaneous injection, in the hope of raising his neutrophil count so that his dose of Interferon could be increased.<sup>91</sup> His dose of Interferon was increased on 13 October 2005. At this time Stephen had a rash on his abdomen from the injection sites, had mild ascites (the accumulation of fluid in the abdomen) and was obviously jaundiced. He was prescribed Spironolactone 50 mg daily for fluid retention.<sup>92</sup>

#### *Deterioration in Stephen's condition and his admissions to hospital*

**6.39** On 17 December 2005 Stephen was admitted to hospital. On that morning he had passed a black stool and begun to vomit a large quantity of blood. On his admission to hospital his treatment with Interferon and Ribavirin was stopped. By this time Stephen had completed 37 weeks of this treatment. Stephen was noted as having been unwell for two weeks. He was lethargic, had a sore throat and dry mouth and his oral intake had reduced. Stephen was found to have bleeding from oesophageal varices and septicaemia. Stephen's condition deteriorated and he went into a coma. A couple of days after Stephen's admission to hospital, the treating doctor told Stephen's wife that Stephen had only a 40% chance of survival.<sup>93</sup> Stephen was treated with intravenous antibiotics for staphylococcus in his blood. He underwent injection sclerotherapy (a procedure to treat blood vessels by injecting a solution into them) of his oesophageal varices and underwent two banding sessions (endoscopic placement of bands over the varices).<sup>94</sup> He was found to have herpes simplex pharyngitis and this was treated with IV Acyclovir. He had hepatic decompensation with ascites and encephalopathy (damage to the brain characterised by confusion, cognitive impairment and lethargy) which required drainage, then control with diuretics. He had hypoalbuminaemia (abnormally low levels of albumin) and his INR, a measure of blood coagulation, rose to 2.7 at its worst. He developed a degree of renal impairment.<sup>95</sup> He did not regain consciousness until 26 December 2005.

**6.40** On 26 December 2005, a doctor in the GI Bleeding Unit advised Stephen's wife that the longer-term objective was to get Stephen assessed by the SLTU (Scottish Liver Transplantation Unit) in Edinburgh and that this depended on getting him through the current episode. She was told that the short-term objective was to treat the sepsis from which Stephen was suffering and to establish useful nutrition but that, at that time, they were not making progress. It was emphasised to her that the hospital would continue with active management but if Stephen's condition deteriorated, the hospital would have to review the treatment options and resuscitation preference.<sup>96</sup>

**6.41** Stephen made 'a remarkable recovery'.<sup>97</sup> His condition improved with treatment and he was discharged home on 17 February 2006. In his subsequent referral letter to the SLTU, his Consultant Physician/Gastroenterologist described this episode as 'a stormy time' and wrote that Stephen 'was very lucky to survive it'.<sup>98</sup>

**6.42** On his return home Stephen was 'very very weak' and was confined to a wheelchair.<sup>99</sup> He had no strength to walk. While he was in a coma Stephen's right knee, which had

<sup>98</sup> Ibid

<sup>99</sup> Day 75, page 64

previously been a target joint (a joint which has repeated bleeding episodes), became stuck in the foetal position. This required intensive physiotherapy and also limited Stephen's mobility. He was unable to do anything himself. Stephen's wife was given leave of absence from her work to care for him. A ramp was installed at their home for the wheelchair. Stephen also required nutritional support but was unable to tolerate a nasogastric tube. He was prescribed nutritional drinks and milk shakes instead. At this time thoughts of his daughter kept Stephen going. There were days when he thought, 'What's tomorrow going to bring?', but he never gave up hope, 'maybe because of the type of person I am' but also because of his family.<sup>100</sup>

**6.43** On 25 February 2006 Stephen was re-admitted to the local hospital with mild encephalopathy secondary to dehydration. He was very confused and did not recognise his family. He was also complaining of back pain. After treatment with lactulose (a laxative used to treat hepatitis encephalopathy) he was discharged home on 28 February.<sup>101</sup>

#### *Stephen's assessment for liver transplant*

**6.44** Stephen was admitted to the SLTU on 23 April 2006 for assessment for liver transplant. During this admission Stephen was found to have moderate to severe aortic incompetence (aortic valve not closing properly) and there was concern that this might represent recent infective endocarditis (infection on one or more valves of the heart) as a result of his recent sepsis. A cardiology opinion was sought and he had an echocardiogram performed. In addition to this, Stephen underwent further investigations for possible renal impairment and diabetes. His viral loads of both HIV and Hepatitis C were checked. Most of these investigations were carried out at the local hospital. During this time Stephen tried to remain positive. It came as a shock to him that he might be diabetic and have a heart murmur.<sup>102</sup>

**6.45** Following these further investigations Stephen was diagnosed with diabetes mellitus type 2.<sup>103</sup> Stephen believes his diabetes was caused by his liver disease and the pressure it put on his pancreas. The echocardiogram suggested mild, perhaps moderate, aortic regurgitation (the aortic blood leaks back into the heart after each contraction as the valve has failed to close completely). These complications were linked to his liver disease.<sup>104</sup> He was put on the liver transplant list in July 2006. His HIV viral loads were checked monthly after this and it was a condition of him remaining on the transplant list that his HIV viral load did not become positive.<sup>105</sup>

#### *Period between Stephen's assessment for liver transplant and undergoing the liver transplant*

**6.46** Between the beginning of March 2006 and the end of January 2007 Stephen was admitted to hospital on 19 separate occasions. Most of these admissions were due to episodes of encephalopathy which gradually worsened over time. He was also admitted on occasion due to ascites and for variceal banding (to reduce the risk of bleeding). During the episodes of encephalopathy, Stephen became drowsy, confused, nauseous, agitated and had spells of vomiting. These episodes must have been very frightening for Stephen's

<sup>105</sup> Day 75, page 69

family, particularly his daughter. Stephen often went into a coma during these episodes for a period of 24 or 48 hours. Stephen used to know when such an episode was coming on and the severity of it depended on how quickly he was admitted to hospital. He was concerned about the long-term impact of such episodes on his brain but was reassured that there should be no impact.<sup>106</sup>

**6.47** He also attended regular review appointments at the SLTU. At an appointment in August 2006, Stephen was noted to be frail, jaundiced and very thin with no nutritional reserve:

I came from a guy who had huge upper body strength to being a guy who could do nothing for himself, in a wheelchair .... I did a lot of weight training, a lot of exercise, and to be struck down within a matter of months into a wheelchair, it's not the best.<sup>107</sup>

Latterly, his consultant told Stephen that he was becoming so weak that he might not survive many more episodes of encephalopathy. Stephen continued to suffer from ascites and eventually attended the hospital weekly to have the fluid drained.<sup>108</sup>

**6.48** Stephen was always told by the surgeons in Edinburgh that he needed 'a good liver'.<sup>109</sup> He was offered the option of a transplant from a living related donor or a close blood match. Such transplants were very uncommon at that time and this perhaps reflects the seriousness with which the surgeons viewed Stephen's condition and their wish to do the best for him. This procedure involves a significant abdominal operation for the donor which carried with it a risk of mortality of about 1%. Due to these risks Stephen never considered this as an option. He felt that he could never have forgiven himself if something happened to a relative like his sister, for the purpose of his survival. Unknown to him at the time, two people offered to be such donors for him, but one person who was subsequently tested was found not to be a match.<sup>110</sup>

### *Stephen's liver transplant*

**6.49** On 31 January 2007 Stephen was told that there was a liver available for transplant. By this time he was so ill he 'just wanted it done'.<sup>111</sup> When he received the telephone call telling him the news, everybody around him was crying and he thought, 'At last'.<sup>112</sup> He was keen to have the surgery carried out and then to try and rebuild his life as he best he could. He was admitted to the RIE that night and underwent various tests. There was concern that Stephen might have an infection as a result of his ascites but thankfully he did not.<sup>113</sup>

**6.50** On 1 February, Stephen underwent a liver transplant at the SLTU. During the surgery he was transfused with 17 units of white cell concentrate and a number of units of Factor VIII due to his haemophilia.<sup>114</sup> Following the surgery Stephen made good progress. Eight days after the procedure, an Infectious Disease Specialist prescribed Stephen triple combination antiviral therapy for HIV, namely Abacavir 300 mg, Lamivudine 150 mg

---

<sup>106</sup> Ibid, pages 69–72

<sup>114</sup> Ibid, page 77; Excerpts from the medical records recovered in respect of Stephen

and two tablets of Kaletra, all twice a day.<sup>115</sup> Unfortunately, but not unexpectedly, this therapy led to drug interaction with tacrolimus, the immunosuppressant which Stephen was also prescribed following the surgery to prevent rejection of the transplanted liver. As a result of this Stephen developed tacrolimus toxicity. His dose of tacrolimus was withheld for a period and then restarted at a reduced level. In addition to the tacrolimus toxicity, Stephen's recovery from surgery was also complicated by development of renal impairment secondary to a combination of urinary sepsis and tacrolimus toxicity. After treatment this improved. Stephen remained extremely physically wasted. He continued to be fed through a jejunostomy tube (a tube surgically placed into the small intestine) in addition to whatever food he managed to take orally. For a while Stephen suffered from symptoms of diarrhoea and abdominal cramping as a result of the jejunostomy feeding. On 23 February he was transferred from the SLTU to the local hospital where he continued his recovery and received physiotherapy, dietetic input and monitoring.<sup>116</sup> He was discharged home from there on 6 April 2007. One outcome of the liver transplant was that the transplanted liver started producing Factor VIII and so Stephen no longer has haemophilia.<sup>117</sup>

**6.51** Stephen did not make the recovery he had hoped for from the liver transplant. He had a persistent high temperature. Various tests for the cause of this were inconclusive. On 13 April he was readmitted to the local hospital due to worsening peripheral oedema (swelling of the tissues in the lower limbs caused by the build-up of fluid) and marked shortness of breath. On 14 April an echocardiogram showed a grossly abnormal aortic valve and aortic regurgitation. There was also severe right and left systolic dysfunction (failure of the pump action of the heart). The cause of Stephen's aortic valve abnormality was infective endocarditis which had been caused by the septicaemia he had suffered in 2005.<sup>118</sup> Stephen's renal function began to deteriorate.<sup>119</sup> It was felt that Stephen needed urgent aortic valve replacement but the surgeons at the local hospital were extremely concerned about the risks to Stephen of this procedure and were not prepared to proceed with it.

**6.52** On 18 April doctors explained the poor prognosis to Stephen and his wife. They told them that Stephen had two to three days to live. Stephen and his wife were understandably very upset and shocked by this news. At the time of his admission, Stephen and his wife thought that asthma was causing his symptoms and had no idea that they were attributable to his heart. Although they understood why the surgeon would not operate on Stephen, they did not agree with his decision. Stephen slept very little that night as he was very scared.<sup>120</sup>

**6.53** The SLTU was informed of the deterioration in Stephen's condition and agreed to admit Stephen for assessment. On 19 April 2007 Stephen was transferred by 'blue light' ambulance to the RIE. Initially, the surgeons there were also reluctant to undertake the surgery due to the risks involved. However, a further opinion was sought from the Freeman Hospital, Newcastle, and this opinion was that they would proceed with aortic valve replacement. The SLTU asked the Freeman Hospital if Stephen could be transferred

---

<sup>115</sup> Excerpts from the medical records recovered in respect of Stephen; Abacavir and Lamivudine are both nucleoside reverse transcriptase inhibitors and Kaletra is a protease inhibitor. All are used to treat HIV infection.

<sup>119</sup> Day 75, page 80; Excerpts from the medical records recovered in respect of Stephen

<sup>120</sup> Day 75, pages 81–82

there but this was not possible due to a lack of beds in the Intensive Treatment Unit there. Given the disparity of these opinions, a further opinion was sought from Mr Campanella, a Cardiothoracic Surgeon at the RIE. He agreed to carry out the procedure.<sup>121</sup>

**6.54** Stephen believes that, had it not been for his wife, in consultation with Mr Hidalgo, the Consultant Surgeon who performed his liver transplant, he would not have undergone further surgery.<sup>122</sup> His wife insisted on the further opinions. She said she would rather tell her daughter 'that her Dad had died on the operation table than just ... left to waste away until he died at home'.<sup>123</sup> Were it not for his wife and Mr Campanella, he would not be here today.<sup>124</sup>

**6.55** Stephen underwent aortic valve replacement on 26 April 2007. At the time of the surgery, Stephen was six foot three inches in height but weighed less than six stone. Stephen produced photographs of himself at that time for the benefit of the Inquiry, and he was barely recognisable as the man in the witness box. Before the operation Stephen was told '...[w]e need a miracle'.<sup>125</sup> The odds of him surviving the surgery were less than 1% and as Stephen stated, 'You can't get worse odds than that'.<sup>126</sup>

**6.56** After the surgery, Stephen was managed in the Intensive Treatment Unit of the RIE. He required prolonged support there and was very slow to be weaned off ventilation.<sup>127</sup> After a few weeks he was transferred to the High Dependency Unit and latterly to the ward. In July 2007 Stephen was transferred back to the local hospital to continue his recuperation there. At that time the remaining issues in relation to his care were nutrition, monitoring of his diabetes, treatment of the cause of the infective endocarditis, his treatment for HIV and his mobility. He returned to work part-time at the end of July 2007.<sup>128</sup>

**6.57** In the 19-month period between December 2005 and July 2007, Stephen spent 309 days in hospital: 202 of these in his local hospital and 107 in the RIE. This period was 'an extremely traumatic time' for his family; in particular, for his wife and daughter.<sup>129</sup> Stephen's daughter was only about eight years old when he became unwell. Stephen's wife remained with him every day he was in hospital in Edinburgh and so their daughter was looked after by family and friends. She came to visit Stephen in hospital every second weekend but Stephen felt that he 'wasn't nice to look at' so the family protected her from this as best they could. At one point, Stephen and his wife told their daughter that Stephen was going to die. Stephen wanted to tell her as he did not wish this to be left to his wife to deal with. He will never forget her face during this conversation and, to this day, does not know what she was thinking at that time.<sup>130</sup>

**6.58** In her statement to the Inquiry, Stephen's wife said that during Stephen's period of illness, which began in December 2005, they had no family life. From December 2005 onwards, her life revolved around visiting him in hospital every day. She stopped working on 31 October 2006 for a period of 14 months. She stated that they had 'massive' family support throughout, without which she feels they would not have coped. She considered

that she was fortunate to have been able to stay in Edinburgh while their daughter stayed with her grandparents. During that time her daughter's grandparents effectively became her parents. She and Stephen missed a lot of their daughter's life during this time including school concerts and parents' evenings. Their daughter was unable to have friends to stay. She had to grow up very quickly.<sup>131</sup>

### *Stephen's condition now*

**6.59** Stephen has made a full recovery from his symptoms of liver disease and from his heart surgery. He required right knee surgery in June 2008 and a right knee replacement in 2009 to remedy the effects of the contracture of his knee during his coma in December 2005.<sup>132</sup> He continues to attend both the RIE and his local hospital for review and monitoring of his liver, HIV and heart. Initially he underwent blood tests every three months and tests of his heart once a year. Now he has these tests every six months and every two years respectively. His medications have now reduced from 49 tablets a day to 13 tablets – Amoxicillin, Diltiazem, Lansoprazole, Ramipril, Tacrolimus and Kaletra, and insulin injections twice a day for diabetes.<sup>133</sup>

**6.60** Stephen continues to be infected with both HIV and Hepatitis C, although presently he does not think that he has symptoms of either. He has never had any symptoms of HIV and is not aware of any symptoms at present of Hepatitis C.<sup>134</sup> With regard to HIV, his viral load remains persistently undetectable.<sup>135</sup> He is aware that Hepatitis C is more aggressive in a liver transplantee. He knows that at some time in the future he will have to undergo treatment again for Hepatitis C and this is not something he relishes. As he is in a better physical state now, he is hopeful that the side-effects of the treatment will be less severe than those he experienced before.<sup>136</sup> Nonetheless given what Stephen has been through in the past this must be a daunting prospect for him.

### *Specific impacts of Stephen's infection with HIV and Hepatitis C*

**6.61** Stephen came across as a very positive person and as such probably had a tendency to understate the effects of his infection on him.

**6.62** Before he became unwell, Stephen was very active. He was a good golfer with a single figure handicap. His inability to play for four years has affected his golf and he believes that he is not as good as he used to be. Due to the problems he developed with his right knee, Stephen has been unable to resume playing badminton and squash. He is unable to run the distances he ran previously. He is able to weight train but finds it harder to build up to the level he was before, age being a factor in this.<sup>137</sup>

**6.63** Stephen's friends are unaware that he has HIV. They are aware that he has Hepatitis C but this has had no effect at all on their relationship with Stephen.<sup>138</sup>

---

<sup>131</sup> Stephen's wife's Witness Statement

<sup>132</sup> Stephen's Witness Statement.

<sup>133</sup> Day 75, pages 85–86; Amoxicillin is prescribed as prophylaxis to prevent infections in his heart valve, Ramipril and Diltiazem are cardiac medications and Lansoprazole reduces acid in the stomach. As detailed above, tacrolimus is an immune suppressant to prevent rejection of the liver transplant and Kaletra is a protease inhibitor used to treat HIV.

<sup>137</sup> Ibid, page 87; Stephen's Witness Statement

<sup>138</sup> Ibid, page 87

### *Financial impacts*

**6.64** Stephen believes that his ill-health has had a significant impact on his career and on his financial situation. Although Stephen did not suffer any loss of earnings as a result of his periods of ill-health, he believes that he incurred other losses. He normally received an annual bonus. He was paid this the first year he was absent from work but not the second. He believes that this bonus would have been at least £10,000. Stephen also believes that he missed out on promotion and the increased earnings this would have produced. Prior to his illness in December 2005, he was put forward for promotion. He was subsequently advised that, had he not then been absent from work, he would have been successful. This promotion would have resulted in a salary increase of at least £12,000 a year with associated increase of the salary related bonus. He has subsequently been promoted but due to the recession he did not receive the same salary increase as he would have done before.<sup>139</sup>

**6.65** Stephen's employment provides him with a number of benefits which he believes he would lose were he to find another job. He has a staff mortgage which includes life assurance in respect of the mortgage. He has no other life assurance. He believes that due to having HIV and Hepatitis C he would be unable to obtain any other life assurance. In about 1985 Stephen applied for life assurance from Scottish Amicable. His then consultant provided a report in respect of this application. The doctor was then asked by Scottish Amicable to carry out an HTLV-III test on Stephen. Rather than have Scottish Amicable refuse his application, as he thought it would do on receiving his test result, Stephen withdrew his application. Stephen is now anxious not to lose the life assurance he has as he does not wish his wife to be left with the debt of the mortgage, were he to die. He feels that she would have enough to cope with in such a situation without having to sell the house to clear the mortgage. His inability to obtain further life assurance precludes him and his family moving to a bigger house as they might like to do. His desire not to lose this life assurance has prevented Stephen from applying for other jobs which are better paid and have better benefits. He has also turned down a better job with a better salary and benefits.<sup>140</sup> As a result he believes that his ability to further his career has been severely limited by his infections with HIV and Hepatitis C.<sup>141</sup>

**6.66** Stephen's work pension has a death-in-service benefit of four times his salary. Once again Stephen does not wish to lose this benefit and is sure that he would not be able to obtain such a benefit at a new job due to having both HIV and Hepatitis C.<sup>142</sup>

**6.67** Stephen's wife lost earnings of about £7500 during her 14-month absence from work to care for him.<sup>143</sup>

**6.68** Stephen has received payments from both the Skipton Fund and the MacFarlane Trust.<sup>144</sup>

**6.69** Due to his medical conditions, Stephen has had to pay significantly more for travel insurance than his wife each time they have travelled. As an example of this, in October 2011 he had to pay £854 for travel insurance for himself for a three week holiday to

---

<sup>139</sup> *Ibid*, pages 88–89

<sup>140</sup> Additional information provided by Stephen

<sup>142</sup> *Ibid*, page 92; Stephen's Witness Statement

<sup>143</sup> Day 75, page 93

<sup>144</sup> *Ibid*, page 93

America. Some companies will not provide him with travel insurance. Due to his illness he has lost £700 in cancellation costs of a holiday.<sup>145</sup>

**6.70** He and his wife have incurred travel expenses attending hospital and medical appointments. They have also incurred car parking charges which Stephen estimates amount to over £1000. He regularly had to stay overnight in Edinburgh to attend appointments but was able to stay with family.<sup>146</sup>

**6.71** The financial impacts of Stephen's infection with HIV and Hepatitis C and, in particular, Stephen's inability to provide financially, as he would like, for his wife and child in the event of his death appear to be one of the most significant impacts on him of his infection with these viruses. His concerns for their future were he to die show that the uncertainty about his future weighs on his mind.<sup>147</sup>

### **Bridie**

**6.72** Bridie is a civil servant and lives in central Scotland. She has an older sister and a younger brother and gave evidence on behalf of them all about their mother's infection with Hepatitis C and its tragic consequences. Their mother acquired Hepatitis C from a blood transfusion in 1974 and died as a consequence of this on 10 April 2009, aged 62 years. Their father died in 2007.<sup>148</sup> For the purposes of this chapter, Bridie's mother will be referred to as 'Molly'.

### ***Molly's blood transfusion***

**6.73** On 18 October 1974 Molly was admitted to a maternity hospital in central Scotland<sup>149</sup> for the birth of her fourth child. The discharge note of this admission records:

Labour proceeded normally for about four hours when she suddenly took 'a fit' and became unconscious. She developed a marked tachycardia and, on examination was found to be almost fully dilated. At one point cardiac arrest occurred and the patient was resuscitated by external cardiac massage and given intravenous fluids.<sup>150</sup>

**6.74** Molly was then delivered by a low forceps application but sadly the baby girl died about 32 hours later. Molly bled profusely from the vagina and she was transfused in both arms under pressure, with the transfusions barely keeping up with the haemorrhage. Molly received almost three complete exchange transfusions. On examination a large cervical tear was found and a total hysterectomy was performed as this was thought to be the only way to save Molly's life. This surgery was complicated by hypofibrinogenaemia (acute bleeding caused by failure of the blood to clot) interfering with coagulation. During the surgery Molly deteriorated from time to time and for fairly long periods only a faint beat in the aorta could be detected. Initially the anaesthetist had 'great doubts about the recovery of her cerebral function as she remained deeply unconscious for some time'.<sup>151</sup> After the surgery Molly began to improve slowly and steadily. The senior obstetrician and gynaecologist who treated Molly thought that the cause of her collapse was possibly

<sup>148</sup> Ibid, pages 2–3 and page 5

<sup>149</sup> Bridie wishes this hospital to remain anonymous

<sup>150</sup> Day 76, page 6; Excerpts from the medical records recovered in respect of Molly

<sup>151</sup> Excerpts from the medical records recovered in respect of Molly

an amniotic fluid embolism which caused the coagulation defect in the blood.<sup>152</sup> Molly spent some time in the Intensive Care Unit of the maternity hospital before transferring to another hospital where she recuperated. This was a severe, life-threatening episode and there is no doubt that the blood transfusions Molly received contributed to saving her life.

**6.75** Molly suffered long-term effects from this serious event. She became blind in her left eye, suffered weakness in her left hand side and had constant back and abdominal pains. She also became anxious and very worried about hospitals. When she attended an appointment at a hospital in 1988 she had an anxiety attack and felt hot, sweaty and faint at the thought of being in hospital again.<sup>153</sup> This must be borne in mind when considering what Molly subsequently endured as a result of her infection with Hepatitis C.

### *Molly during Bridie's early childhood*

**6.76** As a child Bridie remembers her mother always being at home and everything being tidy and ordered there. Her mother did not work and Bridie and her siblings now believe that this was because she was unwell. They heard that, before they were born, their mother used to be 'the life and soul of the party' but from about 1980 onwards it seemed to them that their mother was always ill and in her bed, except for the odd night out.<sup>154</sup> She complained of sore joints.<sup>155</sup> Their father worked initially in manual type work and then latterly in offices. He worked 14-hour shifts and so, as children, Bridie and her siblings saw him infrequently.

### *Molly's diagnosis with cirrhosis*

**6.77** In January 1992 Molly underwent an ultrasound of her kidneys which revealed coincidentally that she had gallstones.<sup>156</sup> She remained asymptomatic from these until about the middle of 1993 when she started to suffer from right upper quadrant abdominal pain radiating through to her back. On 4 July 1994 Molly was admitted to hospital for a laparoscopic cholecystectomy (removal of her gallbladder). During this procedure the surgeons noticed that she had what appeared to be cirrhosis of the liver. In order to help determine the cause of the cirrhosis the surgeons took a biopsy of her liver. Antibody studies were also carried out. The biopsy revealed changes of micronodular cirrhosis of indeterminate origin but there were some features suggestive of Hepatitis B infection.<sup>157</sup> The discharge note from Molly's admission to hospital records 'The lady herself denied any excess alcohol intake'.<sup>158</sup> It was common at the time for doctors to consider alcohol as a cause of cirrhosis. Molly and her family were shocked that she had cirrhosis and that it might have been caused by excess alcohol. Having had her drink spiked when she was younger, Molly only drank at Christmas time when she had a drink of Advocaat. Molly explained this to the doctors treating her but after she was diagnosed with cirrhosis she felt that she was treated differently by the staff as they presumed that she was an alcoholic. She heard people whispering about her.<sup>159</sup> Molly was mortified by this and very upset. She was told never to drink alcohol again.

<sup>159</sup> Day 76, page 72

**6.78** Unfortunately as alcohol is such a common cause of abnormal liver function test results and liver disease, to this day medical staff and others make incorrect assumptions about patients found to have these. As Professor Hayes stated in his evidence:

[I]t still remains common that people who have abnormal liver tests are referred up to the clinic and they have had a good telling off from their GP about drinking too much alcohol when they insist that they are almost tee-total.<sup>160</sup>

This has been, and remains, a major issue for patients.

**6.79** Molly was told that she required follow-up from a Gastroenterologist and she asked that she be referred privately. She was referred to a Consultant Physician. She saw him in about August 1994. The Consultant Physician noted that Molly had palmar erythema (reddening of the palms) and was mildly jaundiced. Her liver was palpable just below the costal margin (lower edge of the chest). His initial suspicion was that the cirrhosis was caused by a Hepatitis B infection contracted after the blood transfusion she had received in 1974.<sup>161</sup> He also considered primary biliary cirrhosis or chronic auto-immune hepatitis as possible causes. He undertook further investigations of the cause of her cirrhosis including a liver blood test screen and a Hepatitis B surface antigen test but these were inconclusive.<sup>162</sup> The Consultant Physician saw Molly for the third time on 10 October 1994. He noted that she had no symptoms of chronic liver disease although the previous findings on examination persisted.<sup>163</sup> He noted that the latest liver function tests showed continual enzyme disturbance of a mild nature which was not significantly different from her previous visit. He noted also that there were antibodies to Hepatitis B surface antigen present in low titre, indicating a previous infection with an adequate immune response eventually. He concluded that she had developed Hepatitis B at the time of her blood transfusion. He suspected that she subsequently developed chronic hepatitis which damaged her liver although she eventually seroconverted and developed sufficient antibodies to stop the infection progressing. He told her to avoid alcohol and planned to see her at regular intervals. He saw her again in January 1995 when he noted that her liver function test results were not dissimilar to results from her previous visits. As her medical insurance had expired he planned to follow her up at a general hospital.<sup>164</sup> In the event this follow-up did not occur. Molly failed to attend an appointment with the doctor on 18 July 1995 and it seems she made no further appointment with him.<sup>165</sup>

### *Molly's diagnosis with Hepatitis C*

**6.80** In May 1996 Molly attended her GP to have her liver function monitored. As well as carrying out a liver function test, her GP also carried out a screening for Hepatitis C.<sup>166</sup> The result of this was positive. On 31 May 1996 Molly's GP wrote to her and stated:

The repeat liver tests showed no significant change from your previous results. However, I took a blood test to test for a new form of hepatitis recently discovered called hepatitis C. This was positive. It is therefore likely that it has been hepatitis C which is the problem causing your liver abnormalities rather than hepatitis B.<sup>167</sup>

<sup>167</sup> Day 76, page 15; Excerpts from the medical records recovered in respect of Molly

**6.81** Bridie remembers very clearly when her mother found out she had Hepatitis C. Bridie was at home in her garden and her mother and father arrived. Molly said to Bridie, 'I have just been told I'm dying. I have got AIDS'.<sup>168</sup> Bridie stated that this was how her mother took the news that she had Hepatitis C as she did not know what it was and nor did her family. As far as Bridie is aware, Molly was not offered any counselling about the virus at this time.<sup>169</sup>

**6.82** Molly's GP referred her to Dr Datta, Consultant Physician. Molly's first appointment with him was on 26 June 1996. Bridie's father accompanied her to this and all her appointments as Molly was unable to travel to these on her own. Dr Datta found no abnormal clinical signs when he examined Molly. He carried out further blood tests and was of the view that she would need a repeat liver biopsy before a decision was made about treatment.<sup>170</sup>

### *Molly's symptoms of Hepatitis C*

**6.83** Bridie was asked if she thought that her mother was suffering from symptoms of Hepatitis C at the time she was diagnosed with it. In response to this she stated:

[W]e didn't know what the symptoms of Hepatitis C were, so that wasn't until later on, when we discovered what they were, that everything that we knew or we took as being my mum as a normal person was the Hepatitis C obviously ... she had various mood swings and she was constantly tired and she was – I hate to say, she was actually classed as a hypochondriac and she was the joke of the family. Everyone laughed at her and nobody obviously knew until later that it was obviously her illness. Nobody knew she was ill. We just took that to be, that's what she is like.<sup>171</sup>

She further stated:

She was always in her bed. She was always ill. She was always at the doctor's. She was always complaining of being sore, of being tired, of being sick .... I can't remember a time of her being anything other than in bed. She was in bed when I got married and I had my hen do. She was in bed upstairs while everyone was downstairs, and everybody took that to be she wanted to be the centre of attention, and everybody laughed at her. At that time we didn't know any better. We just thought that was what she was like.<sup>172</sup>

**6.84** In February 1997 Molly attended Dr Datta for further review. He carried out liver function tests and noted that Molly's AST (aspartate aminotransferase) and ALT (alanine aminotransferase) levels were marginally better than they were in July 1996.<sup>173</sup> He considered the question of liver biopsy but did not think it necessary at that stage. He also reconsidered Interferon therapy but, having reviewed Molly's liver function test results, decided against it. Dr Datta also considered that, in the near future, the results of the combination trial of Interferon and Ribavirin might give better results for treating Hepatitis C.<sup>174</sup>

<sup>174</sup> Day 76, page 19; Excerpts from the medical records recovered in respect of Molly

**6.85** In March 1997 Molly was referred to Dr Zoma, Consultant Physician in Rheumatology, due to increasing joint pains affecting her shoulders, arms, hands and knees. In his letter of referral her GP noted that Molly ‘appears to be quite limited by her joint pains’.<sup>175</sup> Dr Zoma’s notes of Molly’s first attendance at his clinic on 2 June 1997 record that Molly complained of ‘Generalised aches and pains/cervical spondylosis for “many years”’. Now [complaining of] generalised pains involving neck, shoulders, elbows, hands, hips, knees, feet’.<sup>176</sup> Molly told Dr Zoma that she had difficulty dressing and bathing and that her walking was slow and uncomfortable. Bridie remembers that her mother was unable to walk very far at all and did not even manage to walk to the shop across the road from their house without help. She was always sore and when she did walk she would ‘end up in bed at the end of the day’.<sup>177</sup> Dr Zoma considered that the overall picture was suggestive of an evolving inflammatory arthropathy and wondered if it related to her established active hepatitis. Dr Zoma asked Dr Datta if it was possible for Molly to be prescribed any non-steroidal anti-inflammatory analgesics in view of her liver condition.<sup>178</sup> Although such drugs can affect the liver, Dr Datta agreed that they could be prescribed provided her liver function was monitored. In August 1997 Molly was prescribed Nabumetone 500 mg twice daily.<sup>179</sup> Bridie does not think the medication helped her mother as she remained sore, regardless of what medication she was on.<sup>180</sup>

**6.86** In November 1997, Molly was referred to Dr Morris, Consultant Gastroenterologist as Dr Datta was retiring. On 4 December 1997 Molly attended the nurse-led Liver Assessment Clinic where she was seen by Margaret Neilson, Clinical Nurse Specialist. In her notes about this appointment, Ms Neilson records that she discussed Hepatitis C with Molly ‘at length’ and that Molly was concerned about the possibility of a liver biopsy.<sup>181</sup> Ms Neilson advised her to wait to see if a liver biopsy was necessary. Ms Neilson also gave Molly information booklets about Hepatitis C, information about a support group and contact numbers.<sup>182</sup> Bridie did not know that her mother had been given all this information and was very surprised to learn of it as neither her mother nor her father mentioned it to her.<sup>183</sup>

### *Further investigations which Molly underwent*

**6.87** Molly attended Dr Morris’ clinic on 19 January 1998 where she was seen by a Specialist Registrar. Her liver function test results remained elevated. An ultrasound of her abdomen done in January 1998 showed that her liver was ‘of a patchy echogenicity, with irregular liver capsule suggesting underlying fibrosis’.<sup>184</sup> There was no splenomegaly, varices or ascites. The possibility of a liver biopsy was discussed with Molly but it was noted that ‘she is really not keen on this at the moment’.<sup>185</sup> The ultrasound also revealed that Molly had multiple gallstones in her gallbladder. As she had undergone a cholecystectomy, the presence of gallstones caused some confusion among those treating her. While this

<sup>185</sup> Day 76, page 26; Excerpts from the medical records recovered in respect of Molly. It is not noted that she had had a biopsy at the time of her cholecystectomy in July 1994 which showed cirrhosis

was investigated it also caused Molly some distress.<sup>186</sup> Subsequently, an MRI scan revealed that unusually Molly probably had a second gallbladder which was not removed during the cholecystectomy.<sup>187</sup>

**6.88** On 1 June 1998 Molly attended a clinic appointment with another Specialist Registrar. At this time it was noted that Molly had been reluctant to undergo a liver biopsy as she was unsure of the risks involved.<sup>188</sup> Molly was told that there was a risk of bleeding or even death but that this risk was reasonably low in a patient who is well. She was also told that the test could be done under ultrasound guidance if she wished it as she had multiple adhesions (fibrous bands which form between tissue and organs). Molly agreed to a liver biopsy on this basis. On 8 June 1998 the liver biopsy was carried out. Molly was admitted to the ward at 10 am for the biopsy to be carried out in the afternoon. She was told not to eat or drink anything after 8 am that morning. After the biopsy she was kept in the ward overnight.<sup>189</sup> Given Molly's fear of hospitals this must have been a difficult experience for her. Bridie thought that that her mother found the biopsy painful.<sup>190</sup> The histology report of the liver biopsy noted that there appeared to be 'a moderate increase in fibrous tissue and a suggestion of nodularity ...'.<sup>191</sup> It concluded that 'The overall appearances are entirely consistent with a hepatitis C related chronic active hepatitis'.

**6.89** In November 1998 Molly was prescribed oral Prednisolone for her rheumatoid symptoms.<sup>192</sup> It is unlikely that her bad joint symptoms were related to Hepatitis C. Her general malaise at the time may have been associated with Hepatitis C, or a combination of that and arthritis.

### *Molly's treatment with Interferon and Ribavirin as part of a clinical trial*

**6.90** In March 1999 Molly started treatment with Interferon and Ribavirin. She received this treatment as part of a clinical study entitled 'Viraferon plus ribavirin for the treatment of chronic hepatitis C'.<sup>193</sup> Prior to starting this treatment, Molly signed a Patient Consent Form confirming that she had been given a copy information sheet and the nature, purpose, duration and foreseeable effects of the study had been discussed with her.<sup>194</sup> Being included in a controlled clinical trial did not necessarily mean that the patient received the new treatment, as half of those participating in a trial received the standard treatment and half the new treatment.<sup>195</sup> However, on 9 March 1999 Molly was prescribed 6 million units of Interferon three times per week by subcutaneous injection and Ribavirin 1000 mg daily taken orally.<sup>196</sup> Molly was taught to self-inject. Bridie remembers that her mother 'was never keen on needles' and so this must have been difficult for her.<sup>197</sup> In the event her joint pain made it difficult for her to self-inject and so Bridie's father administered most of the injections of Interferon.<sup>198</sup>

<sup>198</sup> Ibid, page 32

### *The side-effects of treatment which Molly experienced*

**6.91** Molly looked forward to starting the treatment and dreaded it at the same time. She was keen to get rid of the virus.<sup>199</sup> On 15 March 1999, a week after she had started treatment, Molly attended the nurse-led clinic for review. In the notes of this appointment it is recorded that, during the first week of treatment, Molly suffered from general fatigue and sore bones.<sup>200</sup> Her mobility was affected and she had a dull headache which was relieved with paracetamol. She was irritable and emotional. Molly continued to attend this clinic weekly. On 22 March 1999 it was noted that she continued to suffer from the same symptoms as before. On 29 March 1999, three weeks after starting treatment, Molly was noted to be suffering from general fatigue, loss of appetite, weight loss (she had lost four pounds), nausea and a skin rash on her arms and trunk.<sup>201</sup> She was tearful and irritable. Arthritis and general fatigue caused her reduced mobility and her haemoglobin had reduced by 4 gm/dL in two weeks.<sup>202</sup> At this time her dose of Ribavirin was reduced from 1000 mg daily to 600 mg daily and the Interferon from 6 million units to 3 million units three times a week.

**6.92** The notes of the next appointment on 8 April 1999 record that initially Molly felt better on the reduced doses but unfortunately this improvement did not last. She then stopped taking the Ribavirin for a few days and felt better. She described general fatigue, nausea and sleeplessness. It was noted that she was struggling to cope with the treatment. One of the doctors was consulted and he recommended that she stop taking the Ribavirin for a week and increase the dose of Interferon back to its original dose of 6 million units three times a week.<sup>203</sup> A week later Molly reported a marked reduction in side-effects. Her appetite had returned and she was suffering from fewer headaches. So she continued on Interferon monotherapy. Four weeks later, in May 1999, it was noted that Molly was suffering from general tiredness – she was sleeping a lot, and had poor appetite and general aches and pains with arthritis. On 3 June, having completed 12 weeks of Interferon treatment, Molly continued to suffer from fatigue and to sleep a lot. Her platelet count was reduced. Her dose of Interferon was again halved to three million units, three times a week.<sup>204</sup>

**6.93** A virology result dated 18 June, 12 weeks after Molly started treatment, was HCV PCR negative showing that the virus had been cleared. It is unclear if this information was conveyed to Molly. Bridie was unaware of this test result.<sup>205</sup> As a result of the negative PCR test it was planned that Molly continue with treatment with Interferon monotherapy with a view to completing a year's course of it.<sup>206</sup> Molly continued to suffer from general fatigue and to sleep a lot. Bridie recalls that her mother's 'days and her nights were turned round about and ... she was always sore'.<sup>207</sup> Candidly she admitted, 'you tended to listen to my mum and it went in one ear and out the other, because you got to a stage where you got fed up hearing it'.<sup>208</sup> In August 1999 Molly was prescribed sleeping tablets by her GP and

<sup>199</sup> Ibid, pages 31–32

<sup>206</sup> Excerpts from the medical records recovered in respect of Molly

<sup>207</sup> Day 76, page 36

<sup>208</sup> Ibid

she found these helpful.<sup>209</sup> She completed the prescribed Interferon course of 48 weeks of treatment on 14 February 2000. At that time it was noted that the nails on both her hands and her feet were splitting and she was trying to stop taking the sleeping tablets.<sup>210</sup> A month after the treatment had stopped it was noted that Molly remained tired but that her appetite had improved. A further blood test dated 1 March 2000 confirmed that Molly remained HCV PCR negative at the end of her treatment.<sup>211</sup> Once again it is unclear if this result was conveyed to Molly and Bridie was unaware of it.

**6.94** As was standard procedure, a further HCV PCR test was carried out six months after Molly's treatment finished. Unfortunately the result of this test was positive. Molly was told this result at a clinic appointment on 11 September 2000. She attended this appointment with her husband and was seen by a Research Fellow and Sister Neilson. In a letter to Molly's GP about this appointment, the Research Fellow wrote that Molly had 'a tearful reaction to the news' but that they stressed to her the importance of remaining positive.<sup>212</sup>

### *Molly's condition after treatment and her deterioration*

**6.95** Molly continued to attend Dr Morris's clinic for monitoring of her rheumatoid arthritis. The discomfort she suffered from her arthritis and her difficulty sleeping persisted.<sup>213</sup> Doctors from both these clinics liaised about appropriate treatment for her rheumatoid arthritis. Dr Zoma had no doubt that her joint symptoms were linked to her chronic Hepatitis C infection.<sup>214</sup> Around this time she was prescribed low dose Prednisolone, Tramadol (pain relief medication) and Lansoprazole.<sup>215</sup>

**6.96** On 9 September 2002, at Dr Morris's clinic, Molly discussed treatment for Hepatitis C with the Specialist Registrar she saw.<sup>216</sup> The issue of retrying combination therapy was raised. Molly told the doctor that she felt she had not tolerated the treatment before as her sister had recently passed away and she was feeling quite depressed. This suggests that perhaps Molly thought she might tolerate the treatment better under different circumstances and she was obviously keen to try it again. The Specialist Registrar arranged for Molly to be reviewed by the Liver Specialist Nurse so that she could discuss this further. On 28 July 2003, Molly attended an appointment with Dr Morris. He wrote to her GP that he had had a detailed conversation with her about the information she had received at her previous appointment about re-treatment. It was his opinion and that of Sister Neilson that Molly should not be reconsidered for treatment of combination Interferon and Ribavirin because of the marked side-effects that she experienced when this was tried initially. He further wrote, 'I am unclear why her expectations were raised in this manner but have offered my apologies for any undue anxiety caused'.<sup>217</sup> It must have been very disappointing for Molly to believe, for 10 months, that she might receive further treatment when in fact this was not the case.

<sup>215</sup> Prednisolone is a corticosteroid drug used to treat a variety of inflammatory conditions including rheumatoid arthritis; Tramadol is a painkiller used to treat moderate to severe pain; Lansoprazole is a proton pump inhibitor which reduces the amount of acid produced in the stomach.

<sup>216</sup> Excerpts from the medical records recovered in respect of Molly

<sup>217</sup> Day 76, page 39; Excerpts from the medical records recovered in respect of Molly

**6.97** At a review appointment on 12 July 2004, it was noted by a Senior House Officer, that Molly remained asymptomatic from her Hepatitis C.<sup>218</sup> An ultrasound of Molly's abdomen performed in May 2004 was normal and liver function test results showed slight overall improvement. Once again, Molly raised the question of treatment and she asked about Pegylated Interferon therapy. This doctor reiterated that this treatment was not in her best interests as her previous treatment had been unsuccessful and she had also experienced significant side-effects.<sup>219</sup>

**6.98** Around this time Molly started suffering from recurrent urinary tract infections. In 2004 she attended the renal department of the Glasgow Royal Infirmary (GRI) for investigation of this. An abdominal ultrasound in May 2004 demonstrated normal kidneys.<sup>220</sup> She was also found to have high blood pressure and started receiving treatment for this.<sup>221</sup>

**6.99** Molly continued to attend the hospital for monitoring. In 2006 Dr Stanley, Consultant Gastroenterologist, became the consultant in charge of her care. A liver ultrasound in May 2006 showed liver cirrhosis and this was in keeping with her blood tests at the time.<sup>222</sup> The doctor who saw Molly at her clinic appointment on 31 July 2006 discussed the possibility of a liver biopsy to clarify whether or not she was cirrhotic. Molly was not keen on this and said that she would only consider a further liver biopsy if it could be carried out under general anaesthetic. This was not an option and so the doctor proceeded on the assumption that Molly was cirrhotic and, on the basis of this assumption, commenced screening her for varices and hepatocellular carcinoma.

**6.100** Molly underwent an endoscopy on 28 September 2006. The report of this noted that Molly was 'very anxious' and that the endoscopy was 'very poorly tolerated'.<sup>223</sup> The endoscopy revealed four Grade 2 varices.<sup>224</sup> There was no evidence of bleeding. Molly was subsequently prescribed Propanolol as primary prophylaxis in respect of the varices.

**6.101** In 2007 Bridie's father died very suddenly as a result of a heart attack. Until his death he had been Molly's main carer. His death had a significant effect on the whole family. Following his death Bridie took over caring for her mother while also trying to continue with her full-time job. She described this as difficult and when asked to explain what caring for her mother entailed she stated:

It probably would have been easier moving in with her. [O]bviously I had to take her to and from hospitals and doctor appointments. She couldn't do her shopping on her own, so I had to collect her, do her shopping with her. And she couldn't carry anything on her own. She couldn't actually get into the bath and out of the bath. So I had to arrange my time when she needed a bath to actually be in the house to make sure she could get herself organised that way. And I was on 24-hour call almost, just simple things. I think about the

<sup>224</sup> The UK Guidelines on the Management of Variceal Haemorrhage in Cirrhotic Patients (2000) [gut.bmj.com/content/46/suppl\\_1/iii1](http://gut.bmj.com/content/46/suppl_1/iii1). full describes 3 grades of varices – Grade 1 – varices that collapse to inflation of oesophagus with air; Grade 2 – varices between Grade 1 and Grade 3; Grade 3 – varices which are large enough to occlude the lumen (the space in the vein).

only thing she could do was get herself almost dressed and cook herself a bit of dinner. Everything else was me.<sup>225</sup>

**6.102** Molly tended to be wakeful during the night and then mid-afternoon would lie on the couch with a blanket. Bridie and her sister received numerous phone calls from their mother during the night. In retrospect, the reversal of her normal sleep rhythm was a sign of early encephalopathy.<sup>226</sup>

**6.103** Having taken over the care of her mother, Bridie and her siblings realised what their father had endured during the last ten years of his life. Bridie's parents had been together since her mother was 15 years old. Bridie described them as 'lifetime soulmates'.<sup>227</sup> Previously Bridie's father was an active union man with a deep love of politics. He lived life to the full and had an interest in junior football and local pool leagues. He was pool champion and won numerous awards and trophies. He was the focal point of his immediate and extended family. As the burden of caring for Molly began to take its toll on him, his life changed. In March 1998, at the age of 55 years, Bridie's father, who had been unemployed for about a year and looking for work, decided that he needed to stop work and care for his wife due to her deteriorating health.<sup>228</sup> He lost contact with his work mates, stopped socialising with his friends and stopped playing and watching sports. He eventually became 'a virtual recluse'.<sup>229</sup> On one occasion Bridie's father broke down in tears when Bridie's sister was visiting as he was so worried about his wife. Molly confided in Bridie that she had been advised after her diagnosis with Hepatitis C to cease sexual relations and so Bridie's parents close physical relationship ended at that time. Bridie thinks that this affected them profoundly and on a level she will never be able to understand.<sup>230</sup>

### *Molly's diagnosis with hepatocellular carcinoma*

**6.104** In February 2008 Molly's alpha-fetoprotein was found to have risen to 26.<sup>231</sup> As a result of this she attended an urgent clinic appointment with a Specialist Registrar, on 3 March 2008. At this appointment she was noted to have lost a lot of weight. Bridie stated that Molly 'wasn't eating at that point' due to the death of her husband.<sup>232</sup> She underwent an ultrasound scan which showed that the extra-hepatic biliary tree was 'essentially normal'.<sup>233</sup> It was decided at this clinic appointment that Molly should undergo a triple phase CT scan to test for hepatocellular carcinoma. On 28 March 2008 Molly attended for the CT scan. Unfortunately, she was so scared that she ran out of the room without undergoing the scan.<sup>234</sup>

**6.105** On 1 September 2008 Molly attended for a further review with a Specialist Registrar. Bridie accompanied her mother to this appointment. At this time Molly was reported to be 'keeping well'.<sup>235</sup> She had no symptoms or signs of hepatic decompensation and the doctor considered the overall clinical picture to be 'reassuring'. He discussed with Molly her fears about undergoing a CT scan and, in particular, her fear that she would be

<sup>233</sup> Day 76, pages 49–50; Excerpts from the medical records recovered in respect of Molly

<sup>234</sup> Day 76, page 49; Excerpts from the medical records recovered in respect of Molly

<sup>235</sup> Ibid

enclosed during the CT scan. Molly had previous experience of an old-style scanner which she had found extremely claustrophobic. At Bridie's suggestion Molly was able to view the scanner to try to alleviate her concerns about it. She subsequently underwent a second ultrasound scan and had repeat alpha-fetoprotein measured. The ultrasound suggested a 3.8cm left liver lobe lesion. Her alpha-fetoprotein had risen from normal in 2007 to 26 in February 2008, and to 42 in September 2008. Dr Stanley was suspicious that there was liver cancer.

**6.106** She and Bridie then attended a further appointment with Dr Stanley on 23 September 2008. In his letter to Molly's GP about this appointment, Dr Stanley stated that he spoke with Bridie and her mother and explained the suspicion of a primary liver cancer.<sup>236</sup> Bridie was adamant that no one mentioned the suspicion of cancer or used the word 'cancer' to either her or her mother at that time. She stated that she would have remembered had he or someone else done so and she would not have kept it from the rest of her family. In the letter dated 6 October 2008 referred to below, Dr Stanley referred to 'the liver nodule' (another way of describing cancer), and it may be that he used this expression during his discussions with Bridie and her mother as opposed to using the word 'cancer'. At the time of giving evidence, Bridie did not understand what 'liver nodule' meant and accepted it was possible that Dr Stanley had used this expression instead of the word 'cancer' when he spoke to them.<sup>237</sup> During this appointment Bridie was aware that the doctors wished her mother to undergo an urgent CT scan 'because they saw something'.<sup>238</sup>

**6.107** Following this appointment, on 26 September 2008, Molly attended for and underwent a three-phase CT scan. The report of this concluded that there was hepatocellular carcinoma with high suspicion of tumour invasion of the left anterior portal vein.<sup>239</sup> Dr Stanley then wrote to Molly by letter dated 6 October 2008:

We have now reviewed your CT scan in the context of the discussion we had at clinic regarding the liver nodule. The scan remains indeterminate and the unanimous view of those present at the meeting is that you now require an MRI scan of the liver to optimise the information we have prior to discussing treatment options.

I appreciate the difficulties you have tolerating these imaging procedures, but I emphasise that it is extremely important that you attend and undergo the test so that we have all the information required to manage this problem. You should be hearing from the radiologists regarding the date and time to attend for the test, which may be undertaken at Gartnavel due to their speciality interest. Please let me know if there are problems regarding this.<sup>240</sup>

**6.108** On 13 October 2008 Bridie's brother took their mother to the Gartnavel Hospital for the MRI scan. Once again, she was very nervous about the scan because of feelings of claustrophobia. Bridie's brother wore a lead vest and stood by her side throughout. He described the experience as 'very traumatic' for them both.<sup>241</sup> The report of the MRI scan described that Molly 'did not tolerate the procedure very well and the liver specific scans

<sup>241</sup> Day 76, page 54

could not be performed'.<sup>242</sup> The impression given by the MRI scan taken together with the recent CT image was thought to be consistent with a diffuse type hepatocellular carcinoma within segment 3 of the left lobe, extending into the portal vein branch. Molly and Bridie attended an appointment with Dr Stanley on 18 November 2008. Bridie remembers that Dr Stanley told them that they had found a 3cm growth on Molly's liver and that he would refer her to the RIE as that was where the relevant specialist was. He advised them that, due to Molly's age, she would not be a candidate for a liver transplant but they would discuss whether they could cut or burn the growth off. Again, Bridie does not remember the word 'cancer' being used and so she and her mother remained ignorant that her mother had cancer. In his letter to Molly's GP about this appointment, Dr Stanley stated that the recent MRI confirmed the CT findings of 'a likely 8cm diffuse hepatoma in the left liver lobe'.<sup>243</sup> He stated in the letter that he had explained the findings to Bridie and her mother but it appears that the fact that Molly had a liver cancer was not understood by them.

**6.109** On 23 December 2008 Molly, Bridie and her brother attended an appointment with a Consultant Surgeon at the RIE. At this time Bridie and her brother reported to the surgeon that their mother was experiencing episodes of confusion and dizzy spells.<sup>244</sup> The surgeon told them that Molly had hepatocellular carcinoma. This was the first time anybody had mentioned the words 'hepatocellular cancer'.<sup>245</sup> They were all extremely shocked as they had not realised how seriously unwell she was. Molly cried and was inconsolable. Bridie said, 'I think [the Consultant Surgeon] was quite shocked because we were shocked'.<sup>246</sup> The surgeon told Bridie's brother on a one-to-one basis that the prognosis was not good.<sup>247</sup> It was decided that Molly should be referred for chemoembolisation treatment as there were no other available treatment options due to the size of the tumour and vascular involvement.<sup>248</sup> Bridie's brother was told that the success rate of this chemoembolisation treatment was poor, and that Molly probably had about four to six months to live. Molly told Bridie and her brother that she did not know how long she had to live, and had no wish to know so Bridie and her brother decided not to tell her.

### *Molly's treatment for hepatocellular carcinoma*

**6.110** On 18 January 2009 Molly was admitted to the RIE. The chemoembolisation treatment was carried out the following day. Following this procedure Molly was sleepy and sore. On 21 January, Bridie telephoned the hospital and spoke to her mother who seemed to be confused and 'wasn't herself'. On 22 January Bridie's brother visited his mother and was extremely shocked at what he saw: 'she was an old woman who didn't recognise me and couldn't get up from bed'.<sup>249</sup> Bridie's sister visited her mother from England on 23 January and she, too, was shocked and extremely upset to see her mother in such a state. On 27 January Molly was discharged from hospital. On her return home Molly was very difficult to live with. She was confused and aggressive towards Bridie and her siblings.<sup>250</sup> She suffered from mood swings and was unable to carry out simple tasks.<sup>251</sup>

<sup>248</sup> Chemoembolisation treatment involves giving chemotherapy directly into the affected part of the liver and cutting off the blood supply to the tumour. Hepatocellular carcinoma and treatment of it is discussed in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraphs 13.111–13.114.

<sup>249</sup> Day 76, page 59

<sup>250</sup> Excerpts from the medical records recovered in respect of Molly

<sup>251</sup> Day 76, pages 60–61

**6.111** Three days after her discharge from hospital, on 30 January 2008, Molly became very confused. She was unable to dress herself so Bridie and her siblings called an ambulance. Molly threw the paramedics out of her house, but eventually her GP persuaded her to go to the hospital. The GP's letter of referral stated that, as well as becoming more confused and aggressive, she had developed worsening abdominal swelling and leg oedema.<sup>252</sup> An abdominal ultrasound carried out on admission revealed a small amount of ascitic fluid.<sup>253</sup> Molly's encephalopathy was treated with oral Lactulose and she was discharged home on 4 February 2009.

**6.112** At the beginning of February 2009 Bridie's GP signed Bridie off work and she began to care for her mother full-time. Due to the amount of time she spent caring for her mother Bridie saw less of her own son so her partner began to work part-time so that he could help look after him. About this time, Molly started to receive home help twice a day and this help assisted Molly with dressing and meal times. This was funded by the Social Services Department. Initially Molly hated having home help, but then she became dependent on it.<sup>254</sup>

**6.113** Molly had a further admission to hospital between 6 and 11 February 2009 due to symptoms of encephalopathy. At this time she was dark yellow in colour. She was constantly dozing, and her day and night were interchangeable. Her short term memory was affected.<sup>255</sup> A few times her behaviour bordered on violent and, as Bridie stated, 'She wasn't my mum really'.<sup>256</sup> Caring for their mother became a 24-hour occupation for Bridie and her siblings. Molly's GP was a great help to them. Bridie's brother researched other treatment options which might be open to their mother and, as a result of this, Molly went to see a professor at the Beatson Oncology Centre in the hope of being prescribed a drug called Sorafenib.<sup>257</sup> In order to assess if this drug was likely to be of benefit to Molly, he repeated her blood profile to calculate her Child Pugh score.<sup>258</sup> The result of this was 9 and this meant that there was no evidence that Sorafenib would provide any benefit to her.<sup>259</sup> This must have been extremely disappointing news for both Molly and the family to hear.

**6.114** Molly was again admitted to hospital between 16 and 25 March 2009 due to increased confusion, nausea and vomiting.<sup>260</sup> Her family was told that she had only weeks to live. They felt that she had no quality of life in the hospital and so they asked that she be discharged home on 25 March. They took her home in a wheelchair. Molly received palliative care from MacMillan nurses, and various alterations were carried out to the house. These included the provision of a hospital bed, a frame to enable her to use the toilet, a bath lift and chair.<sup>261</sup>

**6.115** As late as March 2009 Bridie's family were unaware of the risk of transmission of the Hepatitis C virus. By this time Molly had semi-constant faecal soiling and her family used to assist her in the hospital, and at home. They were not advised to wear gloves

or aprons and they did not do so when they helped her.<sup>262</sup> As stated above, Molly was provided with information about the Hepatitis C virus and, as Bridie stated, she and her siblings were dependent on their mother to pass on such information.<sup>263</sup>

**6.116** Molly continued to deteriorate. On the evening of 5 April 2009 she became very upset, confused and agitated. She was convinced that someone was going to take her away. She was very frightened and made the comment 'I am not ready for this'.<sup>264</sup> It took Bridie, her sister and the MacMillan nurse to settle her. She required subcutaneous sedation via a syringe driver and then further sedation during the night. The following morning Molly did not wake up as expected and she fell into a coma. She remained in a coma until her death a week later. During this period Bridie stayed at her mother's home, only returning home for an hour each day to see her son. Bridie and her siblings felt unprepared for their mother's death as they had expected her to wake up after being sedated.<sup>265</sup>

**6.117** Bridie and her siblings did not have a good relationship during the 1980s and 1990s. They all felt that they were driven out of the house because everyone's attention was focused on their mother, and they rarely spoke. Their mother's deterioration brought them 'back together' and Bridie stated that they have never been closer.<sup>266</sup>

### *Financial impact of Molly's infection with Hepatitis C*

**6.118** Other than one unsuccessful part-time job in the 1980s, Molly did not work.<sup>267</sup> Bridie believes that her mother would have worked had she not suffered from symptoms of Hepatitis C. This meant that only Bridie's father's salary supported their household and money was tight. When they were younger Bridie and her siblings used to wear second-hand clothes as their parents could not afford new ones. Bridie and her siblings were unable to go on school trips due to the cost of these. Other than visiting relatives in England on a couple of occasions, they had no family holidays. When they left school Bridie and her siblings obtained work so that they could bring money into the family home instead of attending further education. Had she been able to, Bridie would have liked to attend Art school. Her sister would have liked to study catering. Due to his Molly's symptoms of Hepatitis C and his father's main focus being to care for his wife, Bridie's brother's attendance at school was poor. He believed that his parents did not care whether he went to school or not. He left school with few qualifications. He has since obtained various qualifications through his work.

**6.119** Molly never claimed unemployment benefit. When Bridie's father stopped working, Molly applied for Disability Living Allowance and was awarded the lower rate of this allowance. On numerous occasions Bridie's parents had to borrow money from family members to pay the mortgage and to buy food. After her father made the decision not to work again, in 1998, Bridie's uncle paid off the mortgage on Bridie's parents' house so they no longer worried about losing their home. He also gave them money to buy a car so that Bridie's father could drive his wife to her hospital appointments. Bridie and her siblings used to give their parents money for food, bills, car repairs and petrol. When Bridie's parents cared for Bridie's son, Bridie used to bring food and anything else he might need so her parents did not need to buy it.

<sup>262</sup> Ibid, pages 70–71; Bridie's brother's Witness Statement

<sup>263</sup> See paragraph 6.86

<sup>264</sup> Bridie's brother's Witness Statement

<sup>265</sup> Day 76, page 65; Bridie's brother's Witness Statement

<sup>266</sup> Day 76, pages 65–66

<sup>267</sup> Submission by Thompsons received with letter dated 26 May 2011

**6.120** Bridie's parents had no pension and no life assurance as they could not afford either. On the few occasions that her parents went on holiday, her mother travelled without travel insurance. Her parents incurred the expenses of her mother's prescriptions until she was 60 years old, petrol for travelling to and from medical appointments and extra heating costs. Molly felt the cold and so their house used to be kept very warm. During the last 18 months of their mother's life, Bridie and her siblings incurred significant expenses, namely the cost of petrol both driving Molly to and from medical appointments, visiting her in hospitals – including the RIE, hospital car parking charges and the cost of buying food for their mother, as she would not eat hospital food. Each of the children, at some point, took time off work to care for their mother. Bridie used annual leave for two weeks before being signed off work sick to care for her mother. She estimated that she lost about £150 a month, for at least two months, in flexi-time payments. She used up her sick pay entitlement during the period she cared for her mother. This affected her rate of sick pay afterwards and meant that, for a while, she felt unable to take any time off work sick. Bridie's sister incurred travel costs from her home in England to visit and to care for her mother. She too took sick leave from work to care for Molly. The time she spent caring for her mother used up her entitlement to sick leave and so when she was absent from work subsequently, she was only entitled to Statutory Sick Pay.

**6.121** Molly received two payments from the Skipton Fund.

### Colin

**6.122** Colin was 57 years old when he gave evidence to the Inquiry. He is married and he and his wife have three grown-up children. He lives in Scotland.<sup>268</sup>

**6.123** Colin is the third of four brothers. He had Haemophilia B, as did two of his three brothers. All three brothers with Haemophilia B contracted Hepatitis C from their treatment with blood products. Both of Colin's brothers have received treatment for the virus, and one has received a liver transplant.<sup>269</sup>

### *Colin's diagnosis with and treatment for Haemophilia B*

**6.124** Colin was diagnosed with Haemophilia B when he was about three years old.<sup>270</sup> As a child, he was treated at Maryfield Hospital, Dundee until 1973 when his care was transferred to Ninewells Hospital, Dundee.<sup>271</sup> He was told that he had severe haemophilia with a clotting factor of less than 1%. He used to carry a green card in case of an accident and this stated that he had severe haemophilia. A letter in his medical records dated 13 November 1973 recorded Colin's Factor IX assay as 8%.<sup>272</sup> It is likely that, as Colin himself stated, his Factor IX assay varied over the years.

**6.125** Colin was first treated for a bleed (in his right ankle) when he was about seven years old, in 1961. He was admitted to Maryfield Hospital. He was treated with rest, a compression bandage with a wire splint and then an Elastoplast stirrup strapping. He remained in hospital for about two weeks.<sup>273</sup> He had a further bleed in the same ankle the following year. He was treated with bed rest and a compression bandage. His foot was then splinted with Kramer wire.<sup>274</sup>

<sup>268</sup> Day 77, pages 2–3

<sup>270</sup> Ibid, page 7; Excerpts from the medical records recovered in respect of Colin

<sup>271</sup> Colin's Witness Statement

<sup>272</sup> Excerpts from the medical records recovered in respect of Colin.

<sup>273</sup> Day 77, page 7; Excerpts from the medical records recovered in respect of Colin

<sup>274</sup> Ibid

**6.126** Having haemophilia did not affect Colin greatly as a child:

I led quite a normal life. At times I didn't even bother about it. I used to play football, which I was told I shouldn't do. Even late on in my teens, I was a good skier. I used to water ski, snow ski, things that you should never do.<sup>275</sup>

**6.127** Colin recalls being admitted to hospital in 1972 when he was 18 years old, due to a bruised and swollen hand. He then received treatment with fresh frozen plasma. Unfortunately, he suffered an allergic reaction to it known as 'Stevens-Johnson syndrome'. This reaction was successfully treated. The discharge letter from this admission states that Colin 'once again' developed an allergic reaction to fresh frozen plasma, suggesting that this may have not have been his first treatment with this product.<sup>276</sup> There is, however, no record in Colin's medical records of an earlier treatment with fresh frozen plasma or any other blood product.<sup>277</sup> As with all haemophilia patients, over the years Colin's treatment became Factor IX instead of fresh frozen plasma. The first note in his medical records of Factor IX being administered is when he had a tooth extracted in 1981.<sup>278</sup>

**6.128** Colin was reluctant to receive treatment for bleeds as in his mind it weakened his immune system. He only went to the hospital for treatment if he had a severe bleed. He thought that if he had a bleed and received Factor IX treatment, the effects of a further 'bump' were more severe than if he had not just had Factor IX.<sup>279</sup> Colin estimates that, prior to 1994 he received treatment for bleeds a maximum of half a dozen times and each time in hospital. Some of these treatments were to cover dental treatment. His longest stay in hospital was three or four days, and there was a period of many years when he was 'never near a hospital'.<sup>280</sup>

**6.129** Colin left school when he was 15 years old. He started working in the men's sales department of a national clothing retailer and in his first year of employment, won the sales person of the year award for the retailer's 52 stores. After 18 months the retailer closed the store where he worked and Colin started his own small clothing company. It was apparent that Colin has a strong and impressive work ethic. He did not let his haemophilia interfere with this: 'when I was working, rather than go and get treatment, I used to go to work with black and blue legs and arms ...'.<sup>281</sup> Colin ran his clothing store for about seven years. Sourcing products involved a fair amount of travelling. Due to the limitations on the income from this clothing shop, Colin also began doing door-to-door deliveries of morning rolls for extra money. He and his brother began producing their own rolls and then they opened a baker's shop.<sup>282</sup> A company in Glasgow later took over the business and Colin became the general manager.<sup>283</sup>

**6.130** In 1994 Colin became very unwell with a high temperature and rigors. He was admitted to King's Cross Hospital, Dundee with a two-week history of malaise and lethargy, and a four-day history of dysuria (painful urination), right loin pain and rigors. He underwent blood tests and urinalysis revealed protein and blood. He was given morphine

for the pain. Colin felt very unwell and stated that he looked so ill that his friends who came to visit him 'didn't think that I was going to be coming out'.<sup>284</sup> He was diagnosed with right pyelonephritis, (a kidney infection) and discharged home after treatment with IV antibiotics on 10 April 1994.<sup>285</sup> With regard to his recovery, Colin stated, 'It actually took me longer to recover from that than it did from my liver transplant. That took so much out of my system that ... my whole body was wasted. It was very difficult'.<sup>286</sup> It took him a long while to build up his strength after this episode.<sup>287</sup>

### *Colin's diagnosis with Hepatitis C*

**6.131** In 1995 Colin and his two brothers were asked to attend Ninewells Hospital, Dundee. When they attended there, they were told that they should be tested for Hepatitis C. A letter dated 29 August 1995 from Professor Cachia, Consultant Haematologist, to Colin's GP, records that Colin attended the hospital on 11 August 1995.<sup>288</sup> It was noted in this letter that Colin had never attended the hospital for regular review as he had few bleeding problems and had enjoyed an active lifestyle without developing any chronic joint problems. It was further noted that Colin had been tested, and found to be negative, for antibodies against Hepatitis B and HIV. A blood sample was taken from Colin at this appointment. The report of the sample dated 15 August 1995 confirms that Colin was found to be positive for Hepatitis C.<sup>289</sup>

**6.132** Colin's two brothers were informed in January 1996 of the results of their blood tests for Hepatitis C. They were both positive. As Colin still had not received the result of his blood test he telephoned the hospital to ask for it. He cannot remember who he spoke to. He told this person that his two brothers had received their results, but he had not received his. Colin was told that if his two brothers were positive for Hepatitis C then 'of course you have got it'.<sup>290</sup> Colin commented, 'It was actually a very short conversation'.<sup>291</sup>

**6.133** Colin and his wife then attended an appointment with Professor Cachia on 19 January 1996. The note of this appointment records that Hepatitis C was discussed fully with Colin, including the risks of developing cirrhosis and hepatocellular carcinoma, monitoring, treatment and the risk of sexual transmission. Colin's abnormal liver function test results were discussed, his ALT at this time being 213. The note also recorded that Colin 'Drinks regularly. Current intake 26 units per week'.<sup>292</sup> Colin disputes that he told Professor Cachia that his intake was 26 units a week. He stated that there were long periods when he did not drink at all and he would never drink that number of units in a week, except 'maybe if I had been away somewhere with the guys for a week' and added: 'with the amount I used to try and work and was working, alcohol was very low in my priority list as far as that's concerned'.<sup>293</sup> Colin was advised of the potential interaction between Hepatitis C and alcohol and advised to stay within the government's current recommendations for alcohol intake.

<sup>291</sup> Ibid, page 21

<sup>292</sup> Excerpts from the medical records recovered in respect of Colin; Day 77, pages 22–23.

<sup>293</sup> Ibid, page 23

**6.134** Colin's wife was subsequently tested for the virus and found to be negative. Colin's Hepatitis C PCR test dated 6 April 1996 revealed that he had Genotype 1a of the virus. Colin was told that this genotype was the easiest to get rid of when in fact it is the hardest genotype to treat.<sup>294</sup> Colin considers that the advice he received about the virus was 'very low key':<sup>295</sup>

We were all told, 'There is bad news and good news. The bad news is you have got Hepatitis C but the good news is you have got a strain of the virus that is a low strain and it will probably never affect you. So go on and lead a normal life'.<sup>296</sup>

Colin stated that it was now 'common knowledge' that in 1992 there was screening of haemophilia patients for Hepatitis C in the Dundee area and that these patients did not know what they were being tested for.<sup>297</sup> He and his brothers were not included in this.

### *Colin's symptoms of Hepatitis C*

**6.135** Colin started to attend the Haematology Clinic, Ninewells Hospital, regularly for monitoring. He reduced his alcohol intake. Colin's health then began to deteriorate.<sup>298</sup>

It was funny how it started to happen. I was losing strength, losing concentration, and I just put it down to maybe having a bug. In my whole life I have never had the flu. I don't know what the flu is. I very rarely take colds. So for being haemophiliac, general illnesses I was never bothered with. But I started getting aching pains, aching joints and it wasn't right. I thought I had a bug for a while.<sup>299</sup>

**6.136** Initially Colin started to have a few bad days once a month. On these bad days Colin felt tired and sometimes had aches and pains too. Then the bad days gradually increased so that he had more bad days in a month than good ones.<sup>300</sup> Colin's liver function tests deteriorated too and the hospital told him that the virus was causing his symptoms. During one 18-month period he suffered from several bouts of cellulitis (a common skin and soft tissue infection caused by bacteria), each requiring antibiotic treatment. By this time Colin had stopped working due to his symptoms.<sup>301</sup> He received incapacity benefit and found living on benefits 'just a nightmare'.<sup>302</sup>

**6.137** In 1998 Colin was referred to a liver specialist, Dr Dillon, Consultant Physician. Colin attended a clinic appointment with him in July 1998. At this time Colin continued to be troubled with lethargy and muscular aches and pains. He also suffered from periods of breathlessness and episodes of severe sweating. Both of these symptoms were investigated but no cause was found. Over time the periods of breathlessness had stopped. At this appointment the option of a liver biopsy was discussed with Colin. He was aware that there was an increased risk to him from such a procedure due to his haemophilia. This risk concerned Colin so he decided that he wanted a biopsy only if his liver function tests were severely abnormal. The option of combined antiviral therapy with Interferon and Ribavirin

<sup>300</sup> *Ibid*, page 28

<sup>301</sup> *Ibid*, page 28

<sup>302</sup> *Ibid*, page 57

as part of a clinical trial was also discussed with Colin. Colin pushed to start treatment as he wished to try anything to stop the decline of his health. As he stated 'being a generally active person, I wanted to try and get the problem resolved, if it could be resolved'.<sup>303</sup>

**6.138** Around this time Colin started taking milk thistle. He did this at his own instigation having read up on hepatitis and the liver. He discovered that this was something which people took to cleanse their liver and to help their liver function. He believes that it helped him.<sup>304</sup>

### *Colin's first course of treatment with Interferon and Ribavirin*

**6.139** In October 1998 Colin started treatment with Interferon and Ribavirin. Colin was told that he was the first haemophilia patient in Ninewells Hospital to receive this treatment. Before starting it he was warned that he would suffer flu-like symptoms. He was also told that it had different effects on different people depending on their basic wellbeing. Initially the treatment did not cause him any problems but after a week he began to suffer side-effects of it. He felt unwell with a feeling of exhaustion and joint aches which were more severe than those he had experienced before. Despite this he was keen, at this stage, to continue with the treatment. By 10 December 1998 Colin was suffering from severe side-effects namely joint pains and aches, muscle weakness and feeling 'completely washed out, weak and exhausted'.<sup>305</sup> The effects were severe enough to make him want to stay in bed sometimes all day, several times a week. At these times he had to crawl to the toilet on his hands and knees.<sup>306</sup> Colin's neutrophil (a type of white blood cell which protects against infection) count also dropped. As a result of this his prescribed dose of Interferon was halved. His white cell count then returned towards the normal level. His liver function test results also returned nearer to normal with his ALT dropping from 283 in June 1998 to 119 at the beginning of November 1998, although these measurements did fluctuate.<sup>307</sup> During this period Colin was assessed as being entitled to Disability Living Allowance.<sup>308</sup>

**6.140** On 6 January 1999 Colin received the result of a PCR test which had been taken the previous December. The result of the test was that the Hepatitis C PCR remained positive which the doctors took as an indication that the treatment was not working satisfactorily.<sup>309</sup> At this point, approximately 12 weeks after starting the treatment, Colin was advised to stop it. He understood that the reason for this was that his immune system 'was so low'<sup>310</sup> but it seems likely that this PCR test result was an important factor in this decision.

**6.141** Colin felt 'devastated' at having to stop the treatment, particularly having seen some positive benefit of the treatment with regard to his liver function test results. However, he knew that he was unable to continue with the treatment as the side-effects were so severe.<sup>311</sup> It took 'quite a while' for the side-effects of the treatment to wear off and some wore off more quickly than others. Following this Colin then had 'a reasonable period of stabilised health ... where I was only suffering from the aches and pains but my wellbeing was good. It seemed to have done some good to the liver function'.<sup>312</sup>

### *Colin's condition after treatment with Interferon and Ribavirin*

**6.142** Colin continued to attend the hospital on a regular basis for monitoring. Around this time Colin felt well enough to resume working. He felt unable to work for someone else due to the days when he was unwell and so he decided to work for himself. He bought a franchise for sweet sales. The sweets had a long shelf life and were pre-packed. He planned to sell the sweets when he felt well enough to do so. He built the business up to be 'quite a reasonably good going business over the months'.<sup>313</sup> After time he employed someone to work alongside him. This person worked the days Colin did not and the business then operated five days a week.

**6.143** In March 1999 Colin underwent an endoscopy to check for varices. This revealed none.<sup>314</sup> As time went on his condition worsened and it was decided that Colin should undergo a liver biopsy to determine the state of his liver. Colin read a Patient Information Sheet about Laparoscopic Liver Biopsy for those with haemophilia which explained the procedure. He understood that it was 'pretty straightforward'; although since he had haemophilia he would be required to remain in hospital for about four or five days after the procedure.<sup>315</sup> Colin underwent the liver biopsy on 19 October 1999. This required him to have two PICC lines (peripherally inserted central catheters) inserted for intravenous access, one for the factor treatment and one for taking blood samples. Unfortunately following the procedure he developed a left axillary (armpit) vein thrombosis, an unusual complication for a person with haemophilia. He was subsequently told that he was the only person on record as having severe haemophilia and developing a thrombosis.

**6.144** Following the biopsy procedure, Colin's face began to swell: 'my face was out about four or five inches'.<sup>316</sup> His mouth was so swollen that he was unable to swallow and he was dribbling. He developed pains in his body. His whole body started to bruise: 'My whole chest was black and blue and down my arm was black and blue ...'.<sup>317</sup> In order to ascertain what was causing these symptoms Colin underwent a number of x-rays but each of them came back normal. After a number of days a venogram (an x-ray of the veins) revealed that Colin had developed a thrombosis. It was difficult for the doctors to treat. He was prescribed tablets to thin his blood and Factor IX to prevent any internal bleeding. Colin was told that if his blood was thinned too quickly then there was a risk of a clot coming away and that this could be fatal. It was a slow process and there were times when Colin was concerned that he would not live. In the event, the treatment was successful and Colin was discharged home on 1 November 1999.<sup>318</sup> He had to be re-admitted to hospital a week later due to a viral infection. He remained in hospital for four days.<sup>319</sup>

**6.145** Colin's liver biopsy revealed appearances consistent with chronic Hepatitis C. The intensity of inflammation corresponded to Grade 2 and the degree of fibrosis to Stage 2.<sup>320</sup> The appearances fell short of cirrhosis.<sup>321</sup>

<sup>320</sup> There are several different scoring and grading systems for liver biopsies and the same numbers are not comparable with another system. The systems used in the UK are the Ishak HAI and the Knodell systems and the Child Pugh grading for cirrhosis. The Hepatitis C Trust [www.hepctrust.org.uk](http://www.hepctrust.org.uk)

<sup>321</sup> Day 77, page 43; Excerpts from the medical records recovered in respect of Colin

**6.146** Colin continued to experience symptoms of the virus:

You never knew from day to day what it was going to be, to be honest, and as I say, you could have three or four days where you thought, 'Oh, there is nothing wrong with me, apart from a few aches and pains,' and you could get up the next morning and you would be just sore all over and sweating and not right, like the flu symptoms again. That's just the way it went.<sup>322</sup>

**6.147** He continued to take a close interest in available treatments for his condition. He gleaned information about this from discussions with Dr Dillon, internet searches and meeting with other people with haemophilia. At the meetings, it appeared to Colin that patients from Glasgow and Edinburgh were better informed than those in his own area. In his oral evidence to the Inquiry, Colin stated that he had heard from Dr Dillon that Pegylated Interferon was likely to become an option to treat Hepatitis C. Dr Dillon told him that it was slow release and the side-effects would be less severe than Interferon. Colin believed that this would be a better treatment option for him as his liver function test results had improved for a while during his previous treatment with Interferon and he believed the severity of the side-effects he had suffered previously had been a factor in stopping the treatment. Colin stated that he 'fought' to be treated with Pegylated Interferon but, initially, the hospital would not give him this treatment due to its expense.<sup>323</sup> Colin sought help from his local MSP and offered to pay for part of the treatment himself. Colin's medical records show that, in fact, the treatment Colin wished to start was Ribavirin monotherapy.<sup>324</sup> Whichever regime it was, this shows that Colin was keen to receive further treatment for Hepatitis C and was very proactive in trying to obtain it.

**6.148** Colin's efforts to obtain further treatment added to the stress which he was already under due to his symptoms of Hepatitis C. In April 2000 Professor Cachia referred Colin to a psychiatrist to give Colin 'the opportunity to discuss his feelings and concerns about his health now and in the future'.<sup>325</sup> In his referral letter Professor Cachia noted that '[Colin's] symptoms have become more and more disabling over the last few months .... [Colin] is very angry about the Hepatitis C infection and the lack of options that we can offer to improve his health at present'. The psychiatrist concluded that although Colin described various depressive features which generally 'wax and wane' with his general health, he did not consider that there was evidence to warrant a diagnosis of co-morbid depressive disorder. He noted that much of Colin's concern centred around uncertainties about his prognosis and possible treatment strategies: 'Consequently, he has not yet made the psychological shifts necessary for him to come to terms with his deteriorating physical health, although I got the impression that this was perhaps now beginning to happen'.<sup>326</sup> Colin stated:

In my mind it wasn't depression, that's obviously why they sent me there. My attitude has always been if there is something wrong then you sort it, but unfortunately I couldn't sort this. It was something that was just getting worse.<sup>327</sup>

<sup>322</sup> Day 77, pages 43–44

<sup>323</sup> Ibid, pages 44–47; Colin's Witness Statement

<sup>324</sup> Excerpts from the medical records recovered in respect of Colin

<sup>325</sup> Ibid

<sup>326</sup> Day 77, pages 47–48; Excerpts from the medical records recovered in respect of Colin

<sup>327</sup> Day 77, page 48

This highlights one of the difficult features of Hepatitis C and its treatment – the inability at times of a patient to take treatment and effectively to tackle the virus head on, no doubt resulting in feelings of helplessness and frustration. This would have been particularly so at a time when new, possibly improved, treatments were recognised but were not yet available.

**6.149** In October 2000 Colin was referred to the Pain Clinic at Ninewells Hospital in relation to the muscular pains he suffered. He was provided with a TENS machine. This seemed to exacerbate Colin’s muscle spasms and so he stopped using it. He was also prescribed Dihydrocodeine. He declined morphine.<sup>328</sup> About this time Colin started to experience what he called ‘shutdown’:

[I]t was like your whole body shut down. Even when I was driving, I could feel that – you were losing the feel of even the steering wheel, and it was just your whole body was on – it was like somebody had flicked a switch and your system wasn’t working. You couldn’t concentrate, you couldn’t think. It was debilitating totally, and that was just the way it was, that – and I could have that two or three times in a week and not have it for a fortnight. It was one of these things that would come and go, and when it came – you could feel it coming on and it was like being partly paralysed but you weren’t ....<sup>329</sup>

#### *Colin’s treatment with Pegylated Interferon and Ribavirin*

**6.150** On 4 May 2001 Colin started treatment with Pegylated Interferon and Ribavirin as part of a trial. Once again he was warned about the side-effects of the treatment. He was also told that, as the first treatment had failed, there was only a slightly higher chance of this treatment being successful. Five days after starting treatment Colin attended the hospital for review. It was noted that, within four to six hours of receiving his first dose of Pegylated Interferon, Colin had shaking, nausea, sweatiness and a feeling of being unwell which waned as the day progressed. He continued to suffer from nausea in the mornings. At this appointment Colin also mentioned that about a week to 10 days before that appointment he had suffered an episode of melaena.<sup>330</sup> Colin then underwent an endoscopy to discount varices as a cause of the melaena, and no varices were found.<sup>331</sup>

**6.151** At his next review on 21 May 2001, it was noted that since the first review Colin had been suffering from increasing side-effects such as chest tightness, palpitations and widespread aches and pains.<sup>332</sup> He was also suffering from lower back pain spreading to his legs, earache, reduced haemoglobin and reduced neutrophils. Analgesia was having little effect. At this time Colin wanted to stop the treatment. He was seen by Professor Cachia and it was decided that Colin should continue taking Ribavirin but skip his dose of Pegylated Interferon that week. It was planned to admit Colin to hospital if these symptoms worsened.

**6.152** One week later Colin was feeling ‘much improved’.<sup>333</sup> He had experienced slight chest tightening and palpitations two to three hours after a dose of Ribavirin. It was

---

<sup>328</sup> Ibid, page 49

<sup>329</sup> Ibid, page 50; In retrospect, this ‘shutdown’ may have been caused by the effect of the Hepatitis C virus on Colin’s brain – see Chapter 13, *Knowledge of Viral Hepatitis Now*, Paragraph 13.18, re ‘brain symptoms’ and brain fog. At that time the ‘brain complications’ of Hepatitis C were only just being recognised.

<sup>330</sup> Melaena is indicated by dark stools with part digested blood, suggesting bleeding from the stomach.

<sup>331</sup> Day 77, pages 51–52; Excerpts from the medical records recovered in respect of Colin

<sup>332</sup> Ibid, pages 52–53

<sup>333</sup> Ibid, page 53

agreed that Colin would continue taking Ribavirin and recommence Pegylated Interferon at a reduced dose. Colin was keen to continue with the treatment.

**6.153** At the review the following week, on 4 June 2001, Colin complained of suffering from chest pain and palpitations after most Ribavirin doses.<sup>334</sup> He had missed a dose of Ribavirin due to these symptoms. He also complained of pain over his abdomen/kidneys and continued to suffer from general aches and pains, joint and muscle pain and sweats which were attributed to Hepatitis C. At this appointment Colin's neutrophils were noted to be reduced. Following discussion with Professor Cachia, it was agreed that due to these side-effects Colin should miss his dose of Interferon and stop Ribavirin. It was planned that Professor Cachia would discuss Colin's treatment with Dr Dillon, Consultant Physician, and the pharmacist. Colin was keen to continue with the treatment and asked especially if he could continue taking Ribavirin only. It was noted at the next review appointment that if Colin's palpitations persisted then consideration should be given to Colin undergoing a 24-hour ECG.

**6.154** At the next review appointment a week later, Colin reported continuing to feel very unwell with kidney pain, palpitations and chest tightness. He had once again stopped taking Ribavirin himself the previous week. Colin stated that due to the side-effects of the treatment and the detrimental effect on his quality of life he wished to stop taking the treatment. He stated 'I knew myself I couldn't continue on it but also once again my immune system got so low that they advised me that even if I wanted to continue it would be unwise'.<sup>335</sup> About five weeks after starting the treatment Colin stopped taking it. It was a difficult decision for Colin to take as, 'I knew that there was nothing else out there. I knew after that there was nothing else going to be able to help me'.<sup>336</sup>

**6.155** After Colin's treatment stopped he felt better for a while. He felt that the treatment had 'done some good'.<sup>337</sup> He continued to experience 'shutdown' episodes. On good days Colin had a tendency to do too much, and this would make him worse:

[I]t's very difficult when you have worked all your life, a lot of time, and worked for yourself, you put a lot of hours in, and to sit and do nothing wasn't in my nature. So if there was anything I could do when I was feeling good, I did it. And of course, I then paid the consequences for it, but as the months past I realised I just had to do nothing and accept it.<sup>338</sup>

### *The deterioration in Colin's health*

**6.156** Once again Colin's health deteriorated. During 2001 Colin was often bed-ridden. He found that he was operating his business from his house, and often from his bedroom. His employee effectively became the full-time worker. In 2002 he reached the difficult decision to sell his sweet sales business. By this time there was little profit left after paying his employee's wages and expenses, '[s]o the headaches and the cashflow outweighed the benefits of the business'.<sup>339</sup> Colin started claiming Incapacity Benefit again and was awarded the higher rate.<sup>340</sup>

---

<sup>334</sup> Day 77, pages 53–54; Excerpts from the medical records recovered in respect of Colin

<sup>335</sup> Day 77, page 55

<sup>337</sup> Ibid, page 56

<sup>338</sup> Ibid, page 57

<sup>339</sup> Ibid, pages 59–60

<sup>340</sup> Ibid, pages 60–61

**6.157** Colin's wife started to spend more and more time caring for him and his illness took its toll on her. She had worked as a classroom assistant for 13 years without a day's illness. She became unwell with the stress of Colin's illness, and by 2004 she had given up working.<sup>341</sup> Although this meant that money became 'exceptionally tight', Colin thinks that his wife having stopped working helped her. For a while, after she had finished her college course, Colin's daughter came to the house every day to give Colin his lunch. Colin's wife attended her GP and he prescribed medication for a period in respect of her stress and anxiety.<sup>342</sup>

**6.158** In March 2004 Colin's symptoms were exhaustion, blotchy skin and generalised arthralgia (joint pain) and myalgia (muscle pain) with associated sweats. His ALT level was 115. An ultrasound scan then revealed evidence of portal hypertension and significant splenomegaly, the spleen measuring 15cm in length. A subsequent endoscopy revealed four barely visible varices and Colin started treatment with Propranolol for these.<sup>343</sup>

**6.159** By July 2005 it was clear that Colin had developed cirrhosis. An ultrasound scan and gastroscopy revealed splenomegaly and gastric varices. Colin wished to meet a hepatologist to discuss the possibility of liver transplantation.<sup>344</sup> On 27 July 2005 Colin attended an appointment with the Specialist Registrar to Dr Dillon.<sup>345</sup> Colin took some clippings from the *Daily Mail* about stem cell transplantation. Dr Cotton explained to Colin that this was at the very early stages of experimentation and was not a routine treatment. Dr Cotton told Colin that he was not yet at a stage where they would consider liver transplantation. It was agreed that Colin would continue to attend the Haematology Department in respect of his Hepatitis C and that he would be seen at the Hepatitis C Clinic as and when required.

**6.160** Colin's condition continued to deteriorate. His wife and family started to notice that when he was talking to them there were gaps in his conversations. He often appeared as if he was drunk when, in fact, Colin had not taken alcohol since 1994: '[o]nce I found out I had a liver problem, I didn't touch alcohol, not even at New Year'.<sup>346</sup> Colin had stopped drinking to make sure that his liver was not being damaged by anything else. At one of his appointments in March 2006, Colin's wife asked about the cause of these episodes. She was told that it was caused by the effect of Hepatitis C on Colin's liver and the build up of toxins in his body.

**6.161** In November 2006 Colin sold his home in order to release equity and down size. By this time his sons had left home. The following month Colin and his wife moved into a residential caravan where they lived until they moved into their new home in April 2007. The selling of his home, which Colin had had built for the family, was a disappointment to both him and his wife:

I mean, you work hard ... you try to build something up. Then really to live as near normal as you can, not extravagant but, if that's what you have got to do, that's what you have got to do. There's no point in getting into debt.<sup>347</sup>

<sup>347</sup> Ibid, page 67

**6.162** The new home Colin and his wife bought was a flat overlooking a river. It was not ideal for Colin, but he was so unwell by this time that he bought it for his wife. He wanted to ensure that, were he to die, his wife would not be left with any debt. By this time Colin was bed-ridden and he described this time as 'the grim period'.<sup>348</sup>

#### *Colin's assessment for liver transplant*

**6.163** In April 2007 Colin was referred to the Royal Infirmary of Edinburgh (RIE) for assessment for a liver transplant. In the following June he was admitted there for tests. Colin stated:

[I] knew that the only way for me to stay alive was to get a transplant. It was as simple as that. It was a daunting prospect but you have to be realistic and look at it and hope that all being well, that I would live through it.<sup>349</sup>

**6.164** Colin underwent numerous tests and scans:

What I wasn't prepared for was the answers on the Friday. I was – my wife was asked to come down, you are taken into a room. You have got all the senior people in front of you and the chap that spoke to me, he said, 'Well, there is no doubt about it, you need a liver transplant.' He said, 'You could get two years, you could live another two years, you might live a year, but I'll give you six months.' And at that you could have picked me up off the floor because although you know you are ill, you are not putting a term on your life ....<sup>350</sup>

**6.165** Colin was put on to the liver transplant list. He had to attend the RIE for regular review appointments. At a review appointment in August 2007, Colin was noted to be jaundiced with low grade encephalopathy.<sup>351</sup> He was also suffering from significant peripheral oedema and fluid retention. Colin had a long discussion at this appointment with the surgeon about the implications of being on the waiting list. Colin knew that there was no guarantee that there was going to be a liver which would be a match so 'it was a waiting game'.<sup>352</sup> He was told that he could not go further than half an hour away from his house. This was not a problem for Colin as he was so unwell by this time that he remained at home. The prospect of Colin being transplanted by means of a non-heart-beating donor (a donor who had just died and whose heart had stopped, as opposed to a donor whose heart beat was being maintained until shortly before the liver is removed) and also having a transplant from a relative was also discussed with Colin. He was unaware at the time but one of his sons asked to be tested by the hospital to find out if he could donate half his liver to his father. In the event these tests were not concluded before Colin received his liver transplant.

#### *Colin's liver transplant*

**6.166** In September 2007 Colin received a telephone call from the Transplant Unit at the RIE telling him that they had a liver available to transplant. He was taken immediately by ambulance to the hospital and prepared for surgery. He was ready to go to surgery when he was told that the liver had arrived and was unsuitable for transplant as it had been drug abused. Colin described this as 'very, very difficult' for him and his family.<sup>353</sup>

<sup>352</sup> Day 77, page 70

<sup>353</sup> Ibid, page 71

**6.167** Colin continued to deteriorate and in the last weeks of October 2007 he became delirious due to hepatic encephalopathy, secondary to dehydration. He was jaundiced and also had ascites. He had bilateral pitting oedema to mid-shin. On 24 October 2007 he was admitted to Ninewells Hospital where he was treated with intravenous antibiotics and an ascitic tap.<sup>354</sup> He remained in hospital until 29 October. During this period Colin's name was removed from the transplant list due the fact that he had an infection. Colin had not realised how jaundiced he was until he saw his skin next to the white shirt of one of the doctors: '[t]hat was when I realised how bad it was'.<sup>355</sup> The hospital wanted Colin to remain as an in-patient but Colin wished to go home as he did not want to die in the hospital. At this time, Colin's name was reinstated on the transplant list.

**6.168** At 9pm on Thursday 1 November 2007 Colin received another telephone call from the transplant unit at the RIE advising him that a liver was available. Colin asked if they could check that the liver was suitable as he did not think that he would survive the trip to Edinburgh and back. He was told that the liver was good. He was then taken to Edinburgh by a 'blue light' ambulance. Within three-quarters of an hour of arriving at the hospital Colin was in theatre. In the early hours of 2 November he received a graft from a non-heart-beating donor. Colin subsequently discovered that his new liver had come from the north of England as all the transplant units in that area were busy carrying out transplants, and so it was surplus: 'it was a lucky day for me'.<sup>356</sup>

**6.169** Colin became independent of infused Factor IX on 4 November and initially recovered 'extremely well'.<sup>357</sup> He felt fine. However, on 7 and 8 November there was deterioration in his liver function test results. Tests revealed that there 'was a kink in the recipient hepatic artery'. Colin's mental state deteriorated and he became quite confused. This gradually settled along with his abnormal liver function test results. Colin was discharged home on 18 November. During his admission it was noted that his glucose levels were elevated before meal times. Colin was told that, as with a number of people who undergo a liver transplant, he had developed type 2 diabetes. He was prescribed Gliclazide. In addition, Colin had to continue taking a number of medications including anti-rejection medications, anti-fungal medications and antibiotics.<sup>358</sup> He continues to take two anti-rejection medications.

**6.170** Colin felt very well after the liver transplant: '[i]t was a big change'.<sup>359</sup> He initially attended the Scottish Liver Transplantation Unit (SLTU) at the RIE weekly for review, then fortnightly and then monthly. He now attends the SLTU's Outbound Clinic at his local hospital every six months for review. He attends the RIE annually for a liver biopsy.

**6.171** In September 2008 Colin returned to work as a manager for a stocktaking company working in large stores. The work was flexible in that Colin was able to tell the company when he was available to work the following month. This could be three or four days a week. Colin loved the work, but as he was working in the management side he had to travel a lot. One day he could be working in Aberdeen, the next Berwick and then back in Aberdeen the following day. Colin started to suffer from joint pain again. He also began to feel unwell at times. Occasionally he had difficulty concentrating as he drove. His hands

<sup>354</sup> Ibid, pages 71–72; Excerpts from the medical records recovered in respect of Colin

<sup>355</sup> Day 77, page 73

<sup>356</sup> Ibid, pages 74–75

<sup>357</sup> Ibid, pages 75–76; Excerpts from the medical records recovered in respect of Colin

<sup>358</sup> Day 77, pages 77–78; Excerpts from the medical records recovered in respect of Colin

<sup>359</sup> Day 77, page 78

became blotchy, and his face puffed up. He found it stressful trying to manage 30 people when he felt unwell. Initially he cut his working hours down to 16 a week, but the travel remained difficult. He left this job to work in a supermarket as a night-shift shelf stocker. He initially worked three nights a week there but found that all he did between shifts was sleep. He then reduced his work to two nights a week. Two or three times he nearly collapsed at work, and so Colin realised 'enough was enough'.<sup>360</sup> He accepted medical advice that working night shifts was significantly contributing to his symptoms, and that he should retire. He retired in late 2010 at the age of 56. Given his strong work ethic, this was difficult for him: '[retirement] doesn't come easy, I can tell you that'.<sup>361</sup>

**6.172** A liver biopsy in November 2008 showed evidence of fatty change which may reflect metabolic causes, for example, diabetes or other causes, such as development of the Hepatitis C virus. It also showed no evidence of rejection. A liver biopsy in November 2009 showed no significant scarring, or fibrosis.<sup>362</sup>

### *Colin's current symptoms*

**6.173** Colin continues to suffer from aches and pains. He is prescribed Tramadol and takes paracetamol to alleviate these. These pains are mostly joint and muscle pains, particularly in his hands. At times they become very 'puffed up'.<sup>363</sup> Also, he stated:

My ankles puff up and it's hard to walk. Then you are not bothered with it, it will go away again. I have always got the shoulders and arm pains. They do not go away, they are there all the time but you get used to that, but to me that's not being ill. That's just having a pain. You just accept that and get on with it.<sup>364</sup>

**6.174** Colin continues to attend the haemophilia meetings, although he no longer has haemophilia. He does so in order that younger people attending the group may see the benefits of a liver transplant.<sup>365</sup>

**6.175** With regard to future treatment, Colin has been told that Ninewells Hospital has funding for the new treatments but that it is the decision of the RIE if he receives either of these treatments or not. The new treatments that Colin referred to are Boceprevir and Telaprevir.

**6.176** It is likely that the addition of these treatments will cause more severe side-effects for patients.<sup>366</sup> These new treatments are discussed in more detail in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.115.

**6.177** When Colin attended a review appointment at the RIE in about March 2011 he spoke to one of the doctors about these new treatments. The doctor seemed cautious about Colin receiving the treatment as 'we don't want to make you ill. We have just made you better'.<sup>367</sup> Colin believes that if he is going to try and eradicate the virus, it is better to take the treatment when he is well. He plans to discuss this again with the doctor at the RIE at his next appointment.

### *Specific impacts of Colin's infection with Hepatitis C*

**6.178** As a result of his infection with Hepatitis C, Colin feels that he has missed a large part of his children growing up. He knows that his daughter, the eldest, was very concerned about him. His sons used to see him in bed ill and bring him cups of tea. There were long periods of time when Colin was unable to do activities with them, such as skiing. He believes that his illness put 'a lot of stress on them'.<sup>368</sup>

**6.179** Colin's close friends knew about his infection with Hepatitis C. His illness had a big effect on his social life. For a number of years he was unable to socialise as he was not well enough to do so. He was unable to go on holidays. He was unable to pursue his hobbies of skiing, sailing, fishing and walking. Since Colin's health has improved he has managed to have a couple of sailing trips.<sup>369</sup>

**6.180** The financial impacts of Colin's infection with Hepatitis C have been described to a certain extent already. The greatest impacts were Colin having to stop working, and being forced to sell his family home to release some capital. In addition, Colin had a small pension. When he became unwell, and stopped working in the mid-1990s he made it 'fully paid up'.<sup>370</sup> Colin has life assurance which he took out before his diagnosis with Hepatitis C. It is a whole-of-life policy. He had a repayment mortgage which has not been affected by his diagnosis with Hepatitis C. He has taken out travel insurance since his diagnosis, but although he disclosed his haemophilia he did not inform the insurers that he had Hepatitis C. He has incurred travel expenses and parking charges, attending numerous hospital appointments both in Dundee and Edinburgh. He has received two payments from the Skipton Fund.<sup>371</sup>

### **Gordon**

**6.181** When Gordon gave evidence he was 65 years of age and he lived with his wife in England. Before he retired he was a senior academic.<sup>372</sup> Sadly, Gordon died in the summer of 2013.

**6.182** Gordon lived in Edinburgh between 1965 and 1985. He acquired Hepatitis C, Genotype 1, from one of a number of blood transfusions he received at the RIE in December 1975 and/or early 1976.<sup>373</sup>

### *Gordon's blood transfusions*

**6.183** In October or November 1975, when Gordon was 29 years old, he had a respiratory tract infection with pleural effusions.<sup>374</sup> On 1 December he was diagnosed with pericarditis (inflammation of the membranous sac surrounding the heart) and was admitted to the City Hospital, Edinburgh.<sup>375</sup> Constrictive pericarditis was diagnosed in mid-December. On 27 December he was transferred to the care of a Cardiothoracic Surgeon at the RIE, for an urgent pericardiectomy (surgical removal of the pericardium). His condition was sufficiently serious to warrant opening the cardiothoracic theatre which was usually closed between

<sup>374</sup> Gordon's Witness Statement; pleural effusions occur when excess fluid accumulates between the two pleural layers, the fluid-filled space surrounding the lungs.

<sup>375</sup> The pericardium is the fluid-filled sac surrounding the heart and the proximal ends of the aorta, vena cava and the pulmonary artery.

Christmas and New Year. Gordon underwent the pericardiectomy on 29 December. He suffered excessive blood loss in the early post-operative period, and required to undergo further surgery on about 29 or 30 December to rectify bleeding from the operation site. About 1.5 litres of blood and clot were removed from the pleural cavities. Gordon received a number of blood transfusions between 29 and 31 December. As Gordon stated, at that time, he was 'distinctly, critically unwell'.<sup>376</sup>

**6.184** Gordon's recovery was complicated by a number of conditions including septicaemia, cardiac arrest, low cardiac output, bilateral pneumothorax, renal failure and a gastric stress ulcer. In January 1976, while still a patient at the RIE, he received a further transfusion of whole blood and packed red cells after a series of haematemeses (vomiting of blood). He was eventually discharged home in mid-March, having first been transferred back from the RIE to the City Hospital, Edinburgh.<sup>377</sup>

**6.185** Gordon accepted that the operation and the associated blood transfusions were 'necessary and potentially life saving procedures'.<sup>378</sup> Although he discussed the risks of the pericardiectomy with the cardiothoracic surgeon, he very much doubted that there were any discussions about the risks associated with blood transfusions. Prior to his surgery, he expected that if he needed a blood transfusion then it would have been available to him.<sup>379</sup>

**6.186** Gordon was told by nursing staff and a number of people who visited him in hospital, including his late mother, that between the pericardiectomy on 29 December 1975 and the series of haematemeses in January 1976 he became severely jaundiced. One of the people from his work who visited him left the ward immediately after he saw him in this condition. His jaundiced state was also noted in a discharge letter from a Registrar to Gordon's GP: 'he developed severe jaundice which was progressive. However the aetiology of this remained obscure although halothane appears to be incriminated'.<sup>380</sup> Halothane was subsequently discounted as a cause for Gordon's jaundice.<sup>381</sup> A likely explanation for this episode of jaundice is that it was caused by 'shock liver', hypoperfusion (decreased blood flow) of the hepatic artery which kills liver cells. This condition often follows major cardiac surgery particularly when there is a very significant fall in blood pressure. Thus, it is unlikely to have been related to Gordon acquiring Hepatitis C from the blood transfusions.

### *Investigation of Gordon's abnormal liver function test results*

**6.187** Gordon's recovery from these operations and subsequent complications, was good. He returned to work in June 1976. He continued to see a General and Gastrointestinal Surgeon at the RIE in respect of gastric symptoms, from which he suffered following the surgery in January 1976. During these follow-up appointments Gordon's liver function tests were found to be abnormal. It was noted that before the pericardiectomy, apart from a minor elevation of alkaline phosphatase, Gordon's liver function tests were normal. In September 1976 the surgeon noted that Gordon's ALT level was raised, at 139. At the suggestion of the surgeon, Gordon subsequently abstained from alcohol for three months, but his ALT level remained elevated.<sup>382</sup>

<sup>381</sup> Halothane is a general anaesthetic drug.

<sup>382</sup> Day 77, pages 103–105; Excerpts from the medical records recovered in respect of Gordon

**6.188** In early 1977, the surgeon referred Gordon to Dr Niall Finlayson, Consultant Physician at the RIE, for his opinion on the cause of Gordon's persistently abnormal liver function tests. Gordon attended to see Dr Finlayson in about March or April of that year. Gordon found Dr Finlayson to be very thorough. Dr Finlayson reviewed Gordon's case notes and examined him. Gordon gained the impression that he was puzzled about the liver function test results and keen to investigate their cause. Tests for Hepatitis B antigen and antibody were negative as were tests for other diseases – Q fever, toxoplasmosis and infectious mononucleosis. At this time Gordon was 'not terribly worried' about his abnormal liver function results although he was 'not entirely happy to see that he had persistent hepatitis'. He was energetic, back at work and 'generally enjoying everything [he] did'.<sup>383</sup>

**6.189** In September 1978 Gordon underwent a liver biopsy. This showed 'a mild persistent hepatitis'.<sup>384</sup> Gordon does not recall being told the results of the biopsy.<sup>385</sup> About this time, Dr Finlayson concluded that non-A, non-B Hepatitis was the most likely cause of Gordon's abnormal liver function test results as he had excluded all other known possible causes. Gordon remembers Dr Finlayson telling him about NANB Hepatitis which at that time was presumed to be viral. He remembers that Dr Finlayson mentioned to him that he was aware of recent research that an agent, just found to be transmissible in chimpanzees, was a possible/probable candidate.<sup>386</sup>

**6.190** Between 1977 and 1982 Gordon continued to attend appointments with Dr Finlayson for monitoring. During that period Gordon did not display any symptoms of NANB Hepatitis. In 1985 Gordon moved to England as he was offered a good position there. After he moved, there was no further monitoring of his condition by the NHS in Scotland. Gordon married in 1987. Before marrying his wife he told her that he had an illness and was not clear what the outcome of it was likely to be.<sup>387</sup>

**6.191** In March 1988, while carrying out an experiment as part of his work, Gordon measured his own blood ALT and found it to be high. He mentioned this to a personal friend, a Consultant Physician, who agreed to take a blood sample and check the ALT level. This doctor subsequently wrote to Gordon and stated that 'the hepatocellular enzymes are indeed quite high and I personally would be a little unhappy to ascribe them to chronic persistent hepatitis'. He suggested that Gordon seek further advice 'as at the very least, they require further monitoring'.<sup>388</sup> Gordon then attended his GP and asked him to refer him to Professor Losowsky, a Gastroenterologist and Hepatologist as well as Professor of Medicine at St James's University Hospital in Leeds. Gordon was acquainted with Professor Losowsky who had told Gordon that he would be delighted to see him. Gordon's GP refused to refer Gordon to Professor Losowsky, and instead advised him to abstain from alcohol. Unsurprisingly, this had no effect on Gordon's ALT levels and at that stage no monitoring of Gordon's liver function was undertaken.<sup>389</sup>

**6.192** Until 1995, Gordon continued in good health and felt remarkably well. He successfully developed his career which he obviously relished and he assumed more responsibilities at work. If he felt tired occasionally, he put this down to having a lot of

---

commitments. He did not worry about his health. As he stated, 'I found plenty to fill every moment and every moment wasn't just for work'. He enjoyed fishing and photography too.<sup>390</sup>

### *Investigation of Gordon's symptoms of Hepatitis C and diagnosis with the virus*

**6.193** In early 1995 Gordon started to suffer from exhaustion. In addition, he lost a considerable amount of weight over two to three months. He attended his GP, who was by now a different GP to the one Gordon saw in 1988. This GP carried out some blood tests, including a liver function test. Gordon returned a week later for the results of these tests and was told that his liver function test results were highly abnormal. From his GP's demeanour, Gordon formed the impression that the doctor thought that the results were very bad indeed. His GP examined him and agreed with Gordon's suggestion that he be referred to Professor Losowsky. At the end of the appointment his GP gave him a strong handshake and it felt to Gordon as if he was saying a final farewell to him. Gordon was very surprised and very shaken by this reaction.<sup>391</sup>

**6.194** Following the referral to him, Professor Losowsky arranged for Gordon to be admitted to St James's University Hospital for full investigation of his weight loss and fatigue. Gordon was admitted there in April 1995 and remained an in-patient for about 19 days while wide-ranging investigations were carried out. As a result of these investigations, which included a liver biopsy, Gordon was told that he had acquired Hepatitis C and that he had cirrhosis of the liver. He 'was not unduly surprised or devastated ... by the Hepatitis C bit, but the fact that I had cirrhosis was very unpleasant ...'.<sup>392</sup> Gordon knew that cirrhosis was irreversible. He did not remember having any discussions with Professor Losowsky, or any other doctor, about the severity of the virus or about its health implications. He was not offered any counselling. Gordon did not feel that the doctors were deficient in this respect, and appreciated that his infection was acquired very early on in the timescale of knowledge of the Hepatitis C virus. Those treating Gordon were aware of his professional background and his ability to access medical information. Gordon would have felt patronised had they spent time explaining the virus to him.<sup>393</sup>

**6.195** The letter written on Gordon's discharge from hospital records that Gordon's alpha-fetoprotein level was found to be significantly elevated, at 200.9. It also records that at that time Gordon was drinking approximately 40 to 50 units a week.<sup>394</sup> Gordon accepted that he was a regular drinker, but considered that these figures were an overestimate of his weekly intake. On his discharge from hospital Gordon was told to abstain from alcohol, which he did for four years.<sup>395</sup>

**6.196** Following his discharge from hospital, Gordon attended out-patient appointments with Professor Losowsky for monitoring. He felt 'optimistic'.<sup>396</sup> In her statement to the Inquiry, Gordon's wife recalled being advised at a subsequent appointment which she attended with Gordon to consider having protected sex. Gordon does not recall this matter being discussed.<sup>397</sup>

### *Gordon's treatment with Interferon*

**6.197** In January 1996 Professor Losowsky offered Gordon treatment with Interferon. By this time his ALT level had increased and Gordon was continuing to feel tired. Professor Losowsky told Gordon that the likelihood of response to the Interferon was small 'in view of his age, duration of disease, presence of cirrhosis and relatively little inflammatory change on the liver biopsy'.<sup>398</sup> Gordon's alpha-fetoprotein level remained raised at 90. A further CT scan of his liver in February 1996 showed no lesions.<sup>399</sup>

**6.198** Gordon and Professor Losowsky agreed that, in order to cause the least disruption to Gordon's work, he should start treatment with Interferon during the Easter holidays. On 2 April 1996 Gordon was once again admitted to St James's University Hospital for a repeat liver biopsy and commencement of treatment with Interferon. The ultrasound-guided liver biopsy showed 'the presence of established micronodular cirrhosis with some portal inflammation consistent with Hepatitis C infection'.<sup>400</sup> The degree of inflammation had not changed since the previous biopsy in 1995. Gordon was commenced on three million units of Interferon, three times weekly. He initially suffered a slight temperature but no other complication was noted. Gordon was discharged home on the same dose of Interferon.<sup>401</sup>

**6.199** During the course of the treatment with Interferon Gordon suffered from substantial fatigue and flu-like symptoms. He found day-to-day living 'a struggle'.<sup>402</sup> The flu-like symptoms did not abate much during the course of the treatment because, as soon as Gordon felt he was recovering from a dose of Interferon, it was time to take the next dose. He 'ached and felt miserable'.<sup>403</sup> He continued to work throughout the course of the treatment. Gordon stopped taking the Interferon treatment after five months as his ALT level remained elevated and he remained HCV PCR positive.<sup>404</sup>

### *The period after Gordon's treatment with Interferon*

**6.200** Gordon continued to attend St James's Hospital for monitoring by Professor Losowsky, and then by his successor Dr Davies, a Consultant Hepatologist. Gordon described his life at this time as 'a progressive struggle' and 'a battle'.<sup>405</sup> He developed considerable tiredness and became more prone to minor infections, such as colds and spots on his skin. Gordon's ability to carry out all aspects of his work began to suffer. In order to fulfil his teaching commitments, Gordon had to reduce the amount of time he spent on research. This must have been very difficult for Gordon as he obviously took great pride in his work, and wanted to carry it out to the best of his ability. In her statement, Gordon's wife describes this period:

From 1995 to about 2001 my husband still managed to work but he suffered from extreme tiredness. He developed sleep problems in that, although he was tired, he was unable to stay asleep. It was a struggle for him to get up in the mornings but he did so in order to go to work as normal .... Intellectually he remained sharp but he was physically exhausted. His appetite was poor and

<sup>403</sup> Ibid, page 129

<sup>404</sup> Ibid, pages 129–130; Excerpts from the medical records recovered in respect of Gordon

<sup>405</sup> Day 77, page 131

he was run down and unable to keep warm, usually having cold hands and cold feet. His condition made spontaneous home and social life minimal. My husband's mood became more thoughtful and introspective but he remained confident, in control, analytical and stoic.<sup>406</sup>

**6.201** In 1996 and 1999 Gordon was found to have minor varices which were ligated or otherwise treated.<sup>407</sup>

**6.202** The possibility of Gordon receiving treatment with Interferon and Ribavirin was discussed with him in 1998 but it was decided that, as he had cirrhosis and had been a non-responder to Interferon, the risks of side-effects of this treatment would outweigh the chance of Gordon deriving any benefit from it. In about 1999 or 2000, Gordon attended an appointment with one of Dr Davies' registrars. Gordon indicated to the registrar that he 'was very tired and not really coping'.<sup>408</sup> Gordon's wife, who also attended that appointment, pressed the registrar about what she proposed to do about Gordon's condition. It seems that she felt a degree of frustration at the fact the doctors were simply monitoring Gordon's condition, and were not treating his symptoms. The registrar suggested to Gordon that, in light of his symptoms, he might require a liver transplant but Dr Davies contacted Gordon the following morning to advise him that the risks of such a procedure would outweigh the benefits. He did, however, make it clear that if Gordon's condition progressed to hepatocellular carcinoma or liver failure his advice would be reversed.<sup>409</sup>

#### *Gordon's diagnosis with hepatocellular carcinoma*

**6.203** In April 2001 an MRI scan and ultrasound revealed that Gordon had probably developed hepatocellular carcinoma. The report of the MRI scan dated 19 April 2001 revealed 'several (5 at least) hypervascular nodules suggestive of HCC'.<sup>410</sup> Gordon was initially told that hepatocellular carcinoma was strongly suspected, with about a 1 in 100 chance of the result having been wrongly interpreted. This was 'perhaps the most drastic thing' Gordon had ever been told about himself.<sup>411</sup> A number of factors mitigated the shock of this news – first, having been aware that his alpha-fetoprotein level was raised and having been referred for both MRI and ultrasound scanning, (which he felt would not have been arranged without some 'serious suspicion'), Gordon knew that hepatocellular carcinoma was 'a possible scenario' and so was 'a little bit prepared' in his mind; secondly, Dr Davies told Gordon about this possible diagnosis 'in a most kindly way'. He telephoned Gordon, saw him and his wife and arranged Gordon's admission to hospital in the same day. Gordon found Dr Davies to be 'incredibly efficient' and his 'middle of the road approach' in giving him this news gave him confidence and 'was a sort of calming influence'.<sup>412</sup>

**6.204** Gordon's wife's reaction to her husband's diagnosis with hepatocellular carcinoma was 'pretty bad'. She was very supportive of Gordon but this was an 'unhappy time' for her. She had been 'tense' since his diagnosis with Hepatitis C.<sup>413</sup>

### *Gordon's liver transplant*

**6.205** Four days after his diagnosis with hepatocellular carcinoma, Gordon was signed off work. On 8 May 2001 he was admitted to St James's Hospital for assessment for liver transplantation and remained there until 11 May. One test was problematic, and Gordon had to wait until a respiratory specialist returned to perform a bronchoscopy on 25 May. Gordon's wife described these weeks as 'harrowing' and added 'the "ifs" and "buts" were too hard for me. I felt helpless and unable to do anything which would change anything. It was like walking on eggshells'.<sup>414</sup> Her father had died of cancer previously which made this time harder for her. She stated:

We were waiting and hoping to be admitted to the transplant list. Another patient came back from seeing a consultant and said to my husband that they could not offer him a transplant and so he was being sent home to die.<sup>415</sup>

Gordon agreed with the proposition that this was a 'very difficult, emotive time' for him and his wife.

**6.206** On 8 June 2001 Gordon was admitted onto the transplant list. He was advised to live normally and keep his bag packed. He remained signed off work. On 30 August Gordon received a telephone call advising him that a liver was available and he was admitted to hospital that night, for surgery at 6 am the next morning. Immediately following the liver transplant Gordon suffered two complications. The first of these was internal bleeding post-operatively. The evening after the surgery, Gordon was 'in considerable pain' and had 'tremendous abdominal tenderness. [He] was just covered with a sheet and if anyone just touched the sheet, [He] would wince in pain...'.<sup>416</sup> An ultrasound scan revealed the cause of this and Gordon was re-admitted to theatre for tying off of some blood vessels and the removal of a blood clot. The second complication was breathing problems which Gordon developed a few days after the transplant. As a result of this, he was taken from the High Dependency Unit to the Intensive Care Unit and was given C-PAP (continuous positive airway pressure) ventilation for a period of time. Gordon stated that he 'did not like' that experience. His wife was 'frightened for him' when she saw him back in the Intensive Care Unit being treated with this form of ventilation. The diagnosis of hepatocellular carcinoma in his explanted liver was confirmed.<sup>417</sup>

**6.207** Thirteen days after the liver transplant, Gordon was discharged home. He was 'delighted to be alive' and 'overjoyed at the success of the operation'.<sup>418</sup> Although Gordon's wife expected him to be confined to his bedroom on his return from hospital, Gordon was keen to be up and about. He returned to work in April 2002. He was very glad to be back and was able to resume most of his work-related activities. At that time his liver function tests were virtually normal, but Gordon had been advised by Dr Davies that it was certain that the Hepatitis C virus would recur.<sup>419</sup>

**6.208** By 2003, Gordon's liver function tests had started to deteriorate and his energy levels were falling. A liver biopsy in October of that year revealed 'considerable portal fibrosis'.<sup>420</sup>

### *Gordon's treatment with Pegylated Interferon and Ribavirin*

**6.209** On 30 January 2004 Gordon started treatment with Pegylated Interferon and Ribavirin. In order that Gordon was able to minimise time spent away from his work, one of the doctors arranged to see Gordon for his regular review appointments just before the start of the clinic at 2 pm. Gordon described the side-effects of this treatment as 'horrendous'.<sup>421</sup> Once again he experienced substantial fatigue which he found particularly troublesome, especially for the first two or three days after each weekly injection. He also suffered flu-like symptoms, nausea, headaches, shortness of breath and aches and stiffness in his knees. He developed a rash which required treatment by a dermatologist. His haemoglobin fell. He lost 7 kilograms in weight. He experienced two episodes of syncope (fainting) which he described as 'very humiliating'.<sup>422</sup> These happened at work in front of a large number of people. The first episode was 'absolutely frightening'. Gordon suddenly became unconscious and hit his head on a bench causing a cut on his head which, as he said, looked worse than it probably was. He was taken by emergency ambulance to the local hospital. A month later the second episode occurred. After this Gordon was told to stop driving until he was reviewed by a neurologist. In order to expedite this review, Gordon arranged to see a neurologist privately. The neurologist concluded that Gordon was unwell and 'the side effects from his treatment have affected him perhaps more than he thought'.<sup>423</sup> After seeing the neurologist Gordon was allowed to drive again. Gordon also attended an appointment with a cardiologist and underwent a 24-hour ECG to rule out the episodes having a cardiological cause.<sup>424</sup>

**6.210** With hindsight, Gordon later considered that he perhaps had misjudged how much he could do while he was taking the Pegylated Interferon and Ribavirin treatment. The episodes of syncope brought home to him what a precarious position he was in while he took the drugs, and the dangerous nature of the treatment. Gordon was also aware that there was some controversy at the hospital as to whether he should be receiving treatment at all, being a non-responder to previous treatment and having received a liver transplant.<sup>425</sup>

**6.211** As there was no drop in Gordon's Hepatitis C viral count, he stopped taking the Pegylated Interferon and Ribavirin treatment after 24 weeks, in summer 2004. He thought that he had recovered fairly quickly from the side-effects of the treatment. As soon as he stopped taking the treatment his weight started to increase and he was 'able to get back to a reasonable life'.<sup>426</sup>

### *The period since Gordon's treatment with Pegylated Interferon and Ribavirin*

**6.212** In 2005, at the age of 59 years, on the advice of those treating him, Gordon took early retirement on the ground of ill-health. It is to his credit that he had managed to continue to work except during his few hospitalisations. Due to the symptoms he suffered, particularly the fatigue, he was unable to fulfil aspects of his work, which damaged his opportunities for career advancement. By 2005 it was clear to Gordon that he 'was not functioning as was essentially required of [him]'.<sup>427</sup> His early retirement, and the fact that

<sup>423</sup> Ibid, page 144; Excerpts from the medical records recovered in respect of Gordon

<sup>424</sup> Day 77, pages 142–143

<sup>425</sup> Ibid, pages 142–144

<sup>426</sup> Ibid, page 146

<sup>427</sup> Ibid, page 147

the last 10 years of his employment were much less productive than he would have liked, was a matter of 'considerable disappointment' and frustration to him. The outlet for his intellectual interests was largely abolished. He found it very hard to adjust after having had a reasonably prolonged career in one area of work, finding that he missed both the work and contact with people in the same field.<sup>428</sup>

**6.213** Since 2005 Gordon had continued to suffer from fatigue, loss of stamina, loss of muscle strength and arthritis and arthralgia. Due to the immunosuppressant treatment he was required to take since the liver transplant, he had suffered some severe dental infections and teeth were extracted as a result of this. In 2007 he was found to have impaired glucose tolerance and, in June 2010, he was diagnosed with diabetes. This is thought to be a consequence of both Gordon's immunosuppression and the Hepatitis C virus. In about 2011, Gordon was diagnosed with interstitial lung disease and the immunosuppression treatment, tacrolimus, was suggested as a possible factor in Gordon's development of this disease. He suffered from breathlessness and, in 2010, had suffered a number of moderately severe chest infections and lost a lot of weight. At the time he gave evidence Gordon was being investigated for pulmonary hypertension. As Gordon stated 'there always seems to be something looming on the horizon, which does seem to have some links going back to either the Hepatitis C virus ... and/or the immuno-suppressant agent'.<sup>429</sup>

**6.214** Gordon continued to attend St James's University Hospital for monitoring. A liver biopsy in August 2010 reported 'recurrent Hepatitis C infection with fibrosis stage 4 and necroinflammatory grade 3'.<sup>430</sup> A Specialist Registrar on the Liver Unit stated in a letter to Gordon's General Practitioner in October 2010 that the Stage 4 fibrosis was unchanged from 2003. He noted that Gordon had moderate inflammation at Grade 4 but overall the biopsy was reassuring and that there has been no progression over the past seven years to cirrhosis. He stated that it was agreed that Gordon would undergo an annual biopsy follow-up although, until he saw a copy of this letter, Gordon was unaware of this.<sup>431</sup>

**6.215** With regard to his prognosis, Gordon was told by Dr Davies when he developed cancer in 2001 that unless he received a successful liver transplant, his condition would be terminal. The prognosis for Gordon's recurrent Hepatitis C was never explained to him except that he was told that it is a progressive disease. Gordon did not ask about his prognosis as he suspected 'the answer is not known ... I feel that nobody knows and nobody will be too surprised if I had an early demise or if I carried on for quite a few years yet'.<sup>432</sup> Gordon had been told about the advent of the new generation of protease inhibitors but at the time he gave evidence had not been told if he was considered a candidate for them. He expected there to be a discussion about this in the near future although he wondered what impact his failure to respond to previous treatment and his age would have had on this.<sup>433</sup>

### ***Specific impacts of Gordon's infection with Hepatitis C***

**6.216** One of the greatest impacts of Gordon's infection with Hepatitis C has been the effect of this on his wife. She has suffered from depression and anxiety since Gordon's diagnosis with hepatocellular carcinoma and his subsequent liver transplant in 2001.<sup>434</sup> Gordon spoke very eloquently and honestly about this. Understandably, he wished part of his evidence on this sensitive matter to be kept confidential, and so not all of what he said is narrated here although it has been considered by the Inquiry.

**6.217** With the benefit of hindsight, Gordon and his wife could see that every individual episode Gordon had experienced as a result of Hepatitis C had imposed an incremental psychological stress on her. This resulted in 'a big change in all sorts of aspects of her behaviour'.<sup>435</sup> Gordon described her experiencing episodes of agitation and becoming jittery, uptight and angry on occasion. She worried and was often quite tearful. There were times when Gordon was an in-patient when he was 'torn because [he] was looking forward to having her as a visitor, very keen to see her, but also dreading that she would react ....'<sup>436</sup> While he liked to read literature about Hepatitis C and followed the progress of this Inquiry, she found this upsetting and it made her feel very anxious. Good friends of theirs noticed the change in her behaviour.<sup>437</sup>

**6.218** In her statement to the Inquiry, Gordon's wife described in detail the distress and anxiety she experienced during each stage of Gordon's illness and, in particular, during the process involved in his liver transplant. At that time, she did not receive any support and she felt ignored because it was her husband who was ill. Each time her husband had an investigation she would become anxious about the procedure and the result. She candidly stated that she had episodes of moodiness and behaved inappropriately at times. 'I fear I embarrass him by my forthright actions sometimes. It is my way of coping ....'<sup>438</sup> She stated:

The care I feel that my husband needs from me is more emotional support than physical help, but I am short-tempered with him and react angrily when events that others see as insignificant happen, and this distresses him further ... I feel that I have lost the ability to support him properly.<sup>439</sup>

**6.219** She acknowledged having felt so low that she did not care if she did not wake up the following day. She stated, 'That is hard to say, think and acknowledge to someone who has been through the diagnosis of Hepatitis C, cancer and a transplant'.<sup>440</sup> Gordon described the times when she expressed an attitude of 'I have had enough. I don't care about anything'. He found it difficult to know how to respond to these episodes.<sup>441</sup>

**6.220** Gordon's wife has been prescribed medication by her GP, undergone a course of cognitive behavioural therapy from a clinical psychologist and attended sessions with a psychiatrist. At the time of the public hearings she was taking a high dose of one antidepressant medication and a moderate dose of another. If she ever forgot to take the medications, 'she [was] really unable to function coherently and very agitated and

<sup>439</sup> Ibid

<sup>440</sup> Ibid.

<sup>441</sup> Day 77, page 158

tearful, very tearful'.<sup>442</sup> All the medical professionals Gordon's wife has seen considered that Gordon's medical history has been a key feature in her depression. Gordon met with his wife's psychiatrist who was of the view that his wife's depression 'was very intimately linked' with Gordon's illness.<sup>443</sup> He also commented to Gordon and in a letter to Gordon's GP that he thought Gordon, too, was suffering a degree of reactive depression although not such as to require intervention. Gordon's wife noticed that his self-confidence was reduced and this too affected Gordon's quality of life. Gordon realised that the events he had experienced as a result of his infection with Hepatitis C have presented a prolonged psychological challenge and he struggled to cope.<sup>444</sup>

**6.221** Gordon's wife's depression had 'an ongoing significant effect' on their quality of life.<sup>445</sup> As Gordon stated 'we have got ... really quite a complicated situation which is not really getting better'.<sup>446</sup>

**6.222** Gordon's wife has had a varied and good career which was affected both by Gordon's illness and by her own depression. She left one job as it involved too much travel and she wanted to remain closer to Gordon. As she began to suffer symptoms of depression, Gordon's wife found her work increasingly difficult. One job ended 'essentially, in tears' as she was not coping and her employers were very unsympathetic.<sup>447</sup> This was clearly a very difficult and stressful time for both of them. At present Gordon's wife is working in a part-time teaching post 'which she is mainly coping with but occasionally, when the going gets tough, she is quite agitated'. This work may be the subject of cut-backs.<sup>448</sup>

**6.223** With regard to the financial impacts of his infection, while he continued to work Gordon did not incur any loss of earnings. This was due both to his admirable strength in continuing to work when he was more than likely unfit to do so, and to the goodwill of his employers. He considered that, but for his illness and the effect of this on his ability to carry out all aspects of his work, he would have had several increments in his salary. Had he been fit to do so, Gordon would have liked to continue working until he was 65 or possibly 67 years old; the latter being an option under his work contract. His pension income was substantially less than his earned income would have been had he been able to continue working. He calculated this cumulative difference to be at least £152,450, not taking account of any increments he might have been awarded. He acknowledged that it was very difficult to assess this loss reliably although considered this figure was likely to be an understatement. At the age of 65 onwards, his superannuation pension was expected to be about £3200 per annum less than it would have been had he been able to continue working.<sup>449</sup>

**6.224** Gordon had also incurred the costs of his own private referral to the neurologist and his wife's private psychiatric referral. He incurred expenses in travelling to the numerous hospital and other appointments he was required to attend. He received both available payments from the Skipton Fund. His mortgage and associated endowment policy were both initiated before his diagnosis with Hepatitis C so these were not affected.<sup>450</sup>

<sup>446</sup> Ibid, pages 153–154

<sup>447</sup> Ibid, page 161

<sup>448</sup> Ibid, pages 160–162

<sup>449</sup> Ibid, pages 162–164; Gordon's Witness Statement

<sup>450</sup> Day 77, page 164

**6.225** Gordon had found that relatively few travel insurance companies were willing to consider insuring someone with his medical history, which obviously included his medical history prior to his diagnosis with Hepatitis C. He found it problematic finding insurance but managed to obtain cover although at a much greater premium than his wife. On one occasion his travel insurance for one week's travel within the UK or Europe was £130 more than his wife's for the same trip.<sup>451</sup>

**6.226** The impacts of Gordon's early retirement have already been stated above. Also, Gordon's activities in retirement reduced from what he had expected due to his limited energy and general arthralgia. This became a further source of disappointment to him. Gordon's hobbies were fly fishing, post vintage and classic cars, photography and Hebridean history. Instead of managing a full day's fishing, he found himself restricted to one or two hours of fishing on rivers and loch banks. He could no longer walk to remote hill lochs to fish. He readily felt the cold and this restricted his outdoor activities. He found it difficult to crawl under his vintage car for basic maintenance, but was able to do some work provided that he rested afterwards. His use of the car was reduced in comparison to before.<sup>452</sup>

**6.227** Gordon wished to put on record that he greatly valued the conscientious attention he received from most of his doctors. He recognised that his survival at 10 years post-transplant was a tribute to a great deal of NHS expertise.<sup>453</sup>

## **Laura**

**6.228** Laura was 47 years old when she gave evidence. She is married with two children and lives in Edinburgh. Her children were born in 1987 and 1992. Laura acquired Hepatitis C from her husband. He has mild Haemophilia A with a Factor VIII level of 32%. Over the years he has been treated with plasma, cryoprecipitate and Factor VIII. As a child, Laura's husband was treated at the Royal Hospital for Sick Children, Edinburgh, and as an adult at the RIE.<sup>454</sup>

### *Laura's husband's diagnosis with Hepatitis C*

**6.229** In 1993 Laura's husband received a letter from the Haemophilia Centre at the RIE advising him that he might have been infected with a virus. Laura's husband had no idea what this letter might be about. He attended the hospital for tests and, at a follow-up appointment in August 1993, was told that he had acquired Hepatitis C. Tests revealed that he had antibodies to Hepatitis C in his blood, but the PCR test did not show the presence of the virus. Laura's husband was told that he had cleared the virus, but continued to attend the hospital for blood tests.<sup>455</sup>

**6.230** At the time he was diagnosed with Hepatitis C, Laura asked her husband if it was possible for the virus to have been passed on. Laura's husband was unsure about this and posed the question to Professor Ludlam, Consultant Haematologist, at the RIE. Professor Ludlam told Laura's husband that the virus 'probably' could not be passed on. His response was in keeping with the state of knowledge at the time about the risk of transmission of the virus. Laura was not offered testing for the virus by the Haemophilia Centre.<sup>456</sup>

<sup>453</sup> Day 77, page 166

<sup>454</sup> Day 79, pages 2-4

<sup>455</sup> Ibid, pages 5-6

<sup>456</sup> Ibid, pages 6-7

### *Laura's diagnosis with Hepatitis C*

**6.231** A few weeks after her husband's diagnosis with Hepatitis C, Laura attended an appointment for one of their children with the family GP. During this appointment, the GP asked Laura generally how the family was. Laura told her about her husband's diagnosis with Hepatitis C. Laura's impression was that the GP did not know much about the virus, but offered her a blood test to put her mind at ease so Laura gave a sample for testing.<sup>457</sup>

**6.232** Laura did not receive the result of this blood test until she attended a routine appointment with her GP about four to six weeks later. At this appointment, she mentioned that she had had the blood test and had not heard anything. The GP replied, 'Oh yes, it came back positive'.<sup>458</sup> Laura was shocked that she had not been informed of the result of this test. She asked the GP about Hepatitis C as she had never heard of it before her husband's diagnosis. Her GP told her that Hepatitis C was known as non-A, non-B Hepatitis but this did not mean much to Laura. She told Laura that the virus could be present in the body for some time before it came to light, but was unsure about treatments for the virus. Laura felt that her GP was not clear what the implications of the virus were. The GP suggested to Laura that she contact the Haemophilia Centre as they might be able to give her more information.<sup>459</sup>

**6.233** Laura took her GP's advice and telephoned the Haemophilia Centre at the RIE. She had known the staff there for some time but she cannot remember who she spoke to on this occasion. Laura informed the person she spoke to that she had tested positive for Hepatitis C. When Laura explained that she thought she had contracted the virus from her husband, that person seemed sceptical and told Laura that this was unlikely. Although the person with whom Laura spoke gave the impression that Laura's infection with Hepatitis C was nothing to do with the Haemophilia Centre, Laura was invited to attend the Centre for a further blood test to 'double-check'.<sup>460</sup> She felt that the Haemophilia Centre was doing her a favour.<sup>461</sup>

**6.234** Laura underwent both a Hepatitis C antibody and PCR test with both coming back as positive. On 17 August 1993 Laura and her husband attended an appointment with Professor Ludlam and Professor Hayes, Senior Lecturer at the Liver Clinic. They explained to her that the virus could cause damage to her liver and Laura agreed to undergo an endoscopy, laparoscopy and liver biopsy. She understood that the liver biopsy would show what effect the virus had had on her liver.<sup>462</sup>

### *Investigations of the source of Laura's infection with Hepatitis C*

**6.235** The Haemophilia Centre undertook further investigations to ascertain if Laura had acquired Hepatitis C from her husband. These investigations included ascertaining her virus genotype to see if it matched her husband's and contacting the Edinburgh and South East Scotland Blood Transfusion Service to ascertain whether she had received a transfusion when she sustained severe lacerations to her hand in 1983. The outcome of the latter investigation was negative. Laura had never heard of genotypes of Hepatitis C and is unaware which genotype of the virus she has. It is not specified in her medical records which the Inquiry recovered. In response to questions by the doctors, Laura told

---

<sup>457</sup> *Ibid*, pages 7–8

<sup>458</sup> *Ibid*, page 8

<sup>459</sup> *Ibid*, pages 8–9

<sup>460</sup> *Ibid*, page 10

<sup>461</sup> *Ibid*, pages 9–10

<sup>462</sup> Excerpts from the medical records recovered with respect of Laura

them that she had had no other sexual partners nor could she have acquired the virus by 'household spread', ie by sharing razors or toothbrushes. Following these enquiries, the source of her infection was not discussed again with Laura but it 'niggled at the back of [her] mind'.<sup>463</sup> In about 1997, Laura asked a Clinical Assistant to Professor Ludlam about how she might have contracted the virus. At that time, the doctor told Laura that they were now aware of a few other cases where the Hepatitis C virus had been transmitted sexually to a partner and so they now realised that 'it was more than likely ... that that was how [she] had contracted it'.<sup>464</sup> This doctor subsequently confirmed on Laura's application form to the Skipton Fund that she had contracted Hepatitis C from her husband.<sup>465</sup>

### *Testing of Laura's children for Hepatitis C*

**6.236** At the time of her diagnosis, Laura and her husband were very concerned that the virus might have been transmitted to their children. This was exacerbated by the uncertainty about how Laura had acquired the virus, and the fact that they knew from their discussions with the doctors that the virus could be transmitted by, for example, the sharing of toothbrushes. Although they did not share toothbrushes, as she said, 'young children sometimes help themselves to things'.<sup>466</sup> Furthermore, their youngest child was only one year old at the time Laura was diagnosed and Laura was worried that she had the virus while she was pregnant. She felt that no-one seemed to know, at that stage, whether in these circumstances there was a risk to her youngest child.<sup>467</sup>

**6.237** At the appointment on 17 August 1993 Laura and her husband asked for their children to be tested for Hepatitis C and the Haemophilia Centre arranged for this to be done. Obtaining a blood sample from Laura's youngest child proved difficult so she was transferred to the special baby unit, at the Simpson Memorial Maternity Hospital, Edinburgh, for this to be carried out. Both children were very upset when their blood samples were taken and Laura and her mother, who took them to these appointments, found the whole experience distressing. Both children were negative for the virus.<sup>468</sup>

### *Laura's symptoms of Hepatitis C*

**6.238** Looking back, Laura thinks she may have been experiencing some symptoms of Hepatitis C in 1992 and 1993. She feels that, following the birth of her second child in 1992, she did not recover or regain the energy levels the way she would have expected to.<sup>469</sup> She felt 'quite run down' during the summer of 1993.<sup>470</sup> She put it down to having a young child at the time.

**6.239** In January 1994 Laura was admitted to the RIE where she underwent an upper GI endoscopy and a laparoscopic liver biopsy. Laura remembers that the endoscopy was 'particularly horrible'. The liver biopsy was 'uncomfortable' and she had mild sedation for this. She remembers being in the theatre for these procedures and she found the whole experience 'quite traumatic'. She was worried about the outcome of both.<sup>471</sup>

<sup>468</sup> Ibid, pages 18–19

<sup>469</sup> Ibid, page 19

<sup>470</sup> Ibid, page 20

<sup>471</sup> Ibid, pages 19–20

**6.240** The endoscopy revealed no evidence of varices. The laparoscopy revealed that the liver was slightly increased in bulk, with yellow areas, suggesting fatty infiltration. The liver biopsy reported 'focal fatty change and a periportal chronic inflammatory infiltrate ... with piecemeal necrosis'.<sup>472</sup> Laura was told these findings at a combined liver clinic with Professor Hayes and Professor Ludlam on 10 February 1994. She remembers that she was told that these findings meant that it was likely that she had been infected with the virus 'for some time'. This upset her. She had previously been told that 'the sort of life expectancy, if you like, from contracting the virus to ... a critical stage was 10 to 15 years'.<sup>473</sup> As these findings suggested that she had had the virus for a while, she felt that her life expectancy was much less than 10 to 15 years. This caused her a lot of distress because she had a young family. She does not remember discussing this with the doctors at that time although she believes that it was apparent to them that she was upset.<sup>474</sup>

### *Laura's treatment with Interferon*

**6.241** The doctors told Laura that Interferon was the only course of treatment available but, given the extent of their understanding about the effectiveness of this treatment at that time, they were unable to give her any guarantees about it. Laura asked what the worst case scenario was if the Interferon did not work. She was told that, in certain cases, if the virus continued to develop that a liver transplant might be necessary.<sup>475</sup> It was agreed that Laura would start treatment with Interferon at a dose of 3 million units three times a week. She was warned to expect flu-like symptoms following the first six to eight injections. She was told that it was usually better to inject the treatment in the evening and to take a couple of paracetamol tablets at the same time in the hope that the symptoms would have subsided by the morning. Laura was warned that a mild degree of depression occurs in some patients but that hair loss is not a problem with such a low dose of Interferon.<sup>476</sup>

**6.242** Laura commenced treatment with Interferon in February 1994. Prior to this she attended the Haemophilia Centre for pre-treatment blood tests and to be shown how to give herself injections of Interferon. As she stated 'the thought of injecting yourself, I don't think appeals to anyone' and she found the treatment 'quite scary'.<sup>477</sup> This was exacerbated by the fact that in order to administer the treatment, she had to break open a glass vial of sterile water. Since sustaining a severe laceration when she put her hand through glass when she was younger, Laura has had 'a bit of a thing about glass'.<sup>478</sup> As a result she was not confident in handling glass. When she was being taught to administer the treatment to herself, she was very nervous opening the vial and cut her finger quite severely. She then had to be 'rushed over' to another part of the hospital for treatment of the finger.<sup>479</sup> Laura found the staff very helpful, and she made the decision that she had to learn to take the treatment and she did so.<sup>480</sup>

<sup>478</sup> Ibid, page 24

<sup>479</sup> Ibid

<sup>480</sup> Ibid, pages 24–25

**6.243** While being treated with Interferon, Laura felt extremely tired. She physically ached, had no appetite and lost weight. She suffered from headaches for which she was prescribed co-codamol. She also suffered from thinning of her hair. She felt generally miserable and depressed, describing herself as feeling 'completely flat'.<sup>481</sup> She 'found everything quite an effort' and she remembers her daughter's birthday party as an example of this.<sup>482</sup> On one occasion her menstrual period was late and the hospital gave Laura a pregnancy test which was negative. As the safety of Interferon for pregnant women was not established, it was recommended that patients use contraceptives while taking it.<sup>483</sup>

**6.244** The treatment had a significant impact on Laura's life. During this time, she was trying to look after her two children, who were then aged about five years and one year, as well as running her own business.<sup>484</sup> She had started this business in the year before her second child was born. She did not want to work full-time, and the business allowed her to work while her husband was at home so that they did not need to find childcare for their daughter. Laura had studied for 18 months and taken the necessary exams to qualify for the work. 'I was so excited about qualifying, just because it was something I had achieved that I had always wanted to do and I enjoyed it'.<sup>485</sup> Laura had built up a good client base for the business by the time she started treatment. The effects of the treatment meant that she found the work 'very difficult'. On one occasion, while with a client, she found herself nodding off, which put both of them at risk. She was very scared and found it frightening 'to be supposedly in control and knowing that you are not in control at all'.<sup>486</sup> Laura's ability to concentrate was also affected by the treatment, and she found it very difficult to maintain her concentration during her work.<sup>487</sup>

**6.245** Laura was certified by her GP as unfit for work from 30 May 1994.<sup>488</sup> Despite this Laura continued to work. She was concerned about financial commitments in respect of her business and the family finances. Laura's husband was working full-time. He realised that she needed more help and found it increasingly difficult to cope. There were times, at weekends, when Laura asked her husband to take the children out swimming or on another activity so that she could have a rest. Laura's parents both worked full-time but they and Laura's sisters tried to help when they could, especially with the children.<sup>489</sup> Looking back at this period now, Laura thinks that she 'wasn't a fun mum at the time. I wasn't very good at maybe spending time with them because I just didn't feel I had the energy ... I did what I had to do ...'.<sup>490</sup>

**6.246** As was standard practice, Laura's Hepatitis C PCR level and liver function were monitored during the treatment. There was usually a delay in receiving the results of these tests and Laura found this a nerve-racking time.<sup>491</sup> Initially, Laura had a good response to treatment – her ALT level halved after two weeks of treatment and then further reduced after four weeks of treatment. However, there was no change to Laura's viral load. Laura recalled that initially it seemed that she had a good response to treatment and she was quite optimistic. However, after eight weeks of treatment Laura's ALT levels rose. There

<sup>481</sup> Ibid, page 25

<sup>482</sup> Ibid

<sup>483</sup> Excerpts from the medical records recovered in respect of Laura

<sup>484</sup> Laura wished the nature of this business to be kept confidential in order to preserve her anonymity.

<sup>485</sup> Day 79, page 26

<sup>486</sup> Ibid, page 26

<sup>487</sup> Ibid, pages 25–27; page 66

<sup>488</sup> Ibid, page 28

<sup>489</sup> Ibid, pages 27–28

<sup>490</sup> Ibid, page 32

<sup>491</sup> Ibid, page 53

was no reduction in quantitative Hepatitis C PCR and after 12 weeks she developed a binding and a neutralising antibody to Interferon.<sup>492</sup> Due to her failure to respond to the treatment, Laura's treatment was stopped after 27 weeks, on 30 August 1994.<sup>493</sup>

**6.247** Laura was devastated that the Interferon treatment had failed and she found this news very difficult to cope with. She felt that, although she was young and had a young family, she was living 'on borrowed time to a certain extent'.<sup>494</sup> No one was able to tell her when another treatment might become available and so she felt that nobody was able to offer her 'a solution or a treatment to give me some sort of hope'.<sup>495</sup> After the treatment stopped, Laura continued to feel 'very low'. She felt unable to shake off a feeling of dread that she felt all the time.<sup>496</sup> She considers that she is quite an optimistic person but 'that was quite a dark time'.<sup>497</sup> She was prescribed anti-depressant medication, Amitriptyline and then Prozac, by her GP to help her sleep. Laura found that that the anti-depressant medication helped a little. A record of Laura's attendance at a clinic appointment in November 1994, three months after she finished Interferon, noted that Laura was tired and seemed down. It noted she had had a lot to cope with over the past year and was working very hard.<sup>498</sup>

#### *The period after treatment and the effect of Laura's symptoms on her business*

**6.248** After finishing the Interferon treatment Laura attended the Haemophilia Centre for regular monitoring. She continued to have both good and bad spells, both physically and emotionally. She was told that she needed to build up her immune system. At these appointments, Laura was advised to give up work to give her body a chance to fight the virus, especially if new treatments became available. Although it was not specifically stated to her, she felt that there was an implication that she had not given the Interferon treatment a chance due to working so hard and being so busy. Laura's parents were also very concerned about her and they, too, tried to encourage her 'to ease up on work' and offered to try to help out financially.<sup>499</sup>

**6.249** Laura continued to work part-time due to financial commitments. However, her condition worsened as time went on and, in 1996, she gave up her business completely. This was a very stressful time for her and her husband. By this time, Laura's business was unable to make the necessary repayments to the finance company which had financed one of her business assets. Laura and her husband were struggling to pay domestic bills and their outgoings exceeded their income. Laura had always been in charge of the family finances and took pride in ensuring bills were paid on time and everything was in order. Other than having a mortgage, she and her husband had never been in debt before, and they found it very distressing to be in debt. Over a number of months Laura negotiated with the finance company with regard to the return of the business asset. She found that this company was not very understanding of her position. It seemed, to her that the company did not want to know what she was going through and the reason she found herself unable to make the payments. When the asset was subsequently repossessed Laura found it 'just terrible'. She felt that she had let everyone down.<sup>500</sup>

<sup>492</sup> Sometimes patients develop a neutralising antibody to Interferon which counteracts its possible beneficial effects.

<sup>500</sup> Ibid, pages 34–36

### *Laura's treatment with Wellferon*

**6.250** In February 1996, at a clinic appointment with Professor Ludlam, two options were discussed with Laura. The first of these was that her Hepatitis C status be monitored every few months and further treatment considered when new drug regimes became available. The second option was for Laura to start on a course of Wellferon, a mixture of alpha interferons. It was noted that there was some evidence that Wellferon was useful in individuals like Laura who developed anti-interferon antibodies. Laura was warned that the side-effects were likely to be similar to her previous treatment.<sup>501</sup> Laura was keen to start treatment as soon as possible so she did not care about the side-effects. 'I would have put up with anything just to be able to start some sort of treatment'.<sup>502</sup>

**6.251** There was a slight delay in starting the treatment to allow Laura time to stop taking Prozac. She was never happy taking Prozac and worried that the longer she took it, the harder it would be to stop taking it. Also, she was concerned that it would interfere with the Wellferon treatment. However, her attempts to stop taking it, at this time, were unsuccessful. 'I wasn't a very nice person when I wasn't on them because I was so down'.<sup>503</sup> So she continued to take this medication.<sup>504</sup>

**6.252** In March 1996 Laura commenced treatment with Wellferon. Once again, she had to inject herself with the medication three times a week. She injected herself in her stomach area, and in her legs, but over time found that she ran out of areas to use. She found the injections increasingly uncomfortable, particularly putting the needle through the skin. She asked the hospital for EMLA cream and found that this helped.<sup>505</sup>

**6.253** Laura felt 'dreadful' during this treatment. She 'functioned on auto-pilot and at times could not get out of bed'.<sup>506</sup> She was constantly tired and irritable. She suffered aches and pains in her neck and shoulders. Eight weeks after she had started treatment, in May 1996, Laura's blood test results were very encouraging. Her ALT had returned to normal and the Hepatitis C virus was undetectable by quantitative PCR test. Laura was aware that the test results were looking positive and that the doctors were pleased with these results. However, by July 1996, her blood test results revealed that she had relapsed. Professor Ludlam and Professor Hayes believed that Laura might benefit from combination therapy of Interferon and Ribavirin. At that time ethical approval was still awaited for the use of Ribavirin in such circumstances. Laura was understandably keen to try this combination therapy.<sup>507</sup>

### *Laura's treatment with Ribavirin and Interferon*

**6.254** In August 1996 Laura commenced treatment with Ribavirin and Interferon as part of a clinical trial. At the same time, Laura stopped taking Prozac for a while as she feared an interaction between it and this new treatment. By this time, Laura had obtained part-time clerical work. Due to their financial situation, Laura felt that she had to earn an income but wanted to find work which was not too big a commitment. This position was a temporary job and was mornings only. Her family helped out with child care.<sup>508</sup> When

<sup>505</sup> Ibid, pages 40–41. EMLA is an anaesthetic cream.

<sup>506</sup> Day 79, page 40

<sup>507</sup> Ibid, pages 41–42

<sup>508</sup> Ibid, pages 40–42 and 44–45

she started this treatment, Laura was aware that the side-effects of it were likely to be similar to those she had experienced from her earlier treatment.

**6.255** Those treating Laura were obviously aware of Laura's mental state and were concerned about this. In a letter to Laura's GP, Professor Ludlam stated that if Laura were to become more depressed on this treatment then 'we must seriously review her Interferon therapy. The difficulty is that she is keen to proceed with treatment and her worry is related to the state of her liver'.<sup>509</sup>

**6.256** In September 1996, Professor Ludlam's Clinical Assistant referred Laura to a consultant psychologist, for psychological help through relaxation and stress management. Laura described her two main problems to the psychologist as being unable to relax, and becoming emotional when she spoke about Hepatitis C.<sup>510</sup>

**6.257** A further matter Laura discussed with the psychologist was the effect of her diagnosis with Hepatitis C on her relationship with her husband. Laura's husband was involved in a serious road traffic accident in about 1988. As a result of this his memory was impaired and, initially, he only trusted Laura. Gradually he recovered, but Laura felt that one of the lasting effects of the accident was that her husband became less responsible. After her diagnosis with Hepatitis C, Laura felt angry that her husband had not asked more about Hepatitis C when he was diagnosed with it. She thought that he should have asked more about what his diagnosis meant and how it could affect her. Also, she considered that he should have asked more questions about his treatment for haemophilia and the implications of it. As a result of this, for a while, Laura blamed her husband for the fact that she had acquired Hepatitis C and thought that perhaps it could have been avoided, had he been better informed about his haemophilia treatment.<sup>511</sup>

**6.258** Laura felt that her husband did not cope well when she was first diagnosed with Hepatitis C:

He kind of stuck his head in the sand and he didn't really want to know. He couldn't cope with it, and I felt I was having to cope on my own and cope with the children and cope with the financial worries as well. And for all those reasons I was quite angry with him at the time. I felt quite let down.<sup>512</sup>

**6.259** Also, Laura felt that she did not get the support she needed from him. For example, she usually cooked all the family meals and her husband does not cook. On the occasions when she did not feel well enough to cook for the family, he did not know what to do, and in the end she had to cook. Laura felt that this, taken together with having had to cope with the after-effects of her husband's road traffic accident, had a major effect on their relationship.<sup>513</sup> In his written statement to the Inquiry, Laura's husband described the strain of Laura's diagnosis with Hepatitis C as having had 'a devastating effect on our relationship'.<sup>514</sup> He stated that 'the guilt I felt for being the one to infect her was almost impossible for both of us to come to terms with'.<sup>515</sup> This guilt must have been compounded by the fact that Laura's husband cleared the virus spontaneously and never suffered any symptoms of it.<sup>516</sup>

<sup>513</sup> Ibid, pages 48–49

<sup>514</sup> Laura's husband's Witness Statement

<sup>515</sup> Ibid

<sup>516</sup> Ibid

**6.260** Another factor contributing to the strain Laura was under was the fact that she did not talk about her condition or treatment to anyone. Other than her parents and sisters, Laura did not tell anyone that she had Hepatitis C or about the treatment she was receiving. Laura felt that if there was anything in the media about Hepatitis C, people often confused it with HIV. People seemed not to know about Hepatitis C and she did not want to start explaining it to people. A further concern to her was that people had the wrong idea about how the virus could be passed on, and she was concerned that this lack of understanding might result in her losing her job.<sup>517</sup>

**6.261** Laura met with the psychologist on a few occasions when she attended clinic appointments. Laura felt that she was not good at accepting counselling as she found it hard to talk to people but benefited from the relaxation tape which the psychologist gave her.<sup>518</sup>

**6.262** The side-effects Laura experienced of Interferon and Ribavirin were 'flu-like symptoms'. She became susceptible to colds. Once again she lost weight.<sup>519</sup> Laura's Hepatitis C RNA became undetectable after starting treatment with Interferon and Ribavirin. By December 1996 her liver function tests were normal. Having relapsed previously after three or four months of treatment, Laura was concerned that this might happen again. However, her blood test results remained normal and when the Interferon and Ribavirin treatment finished, in July 1997, her Hepatitis C PCR remained negative. At this time Laura was told that she was now clear of the Hepatitis C virus. She was told that she would continue to be monitored so that if the virus returned, it could be dealt with. Initially Laura was monitored by the Haemophilia Centre every month, then every three months, then every six months until latterly she was monitored annually.<sup>520</sup>

**6.263** The side-effects of the treatment persisted for a while after Laura had finished it. For a long time after the treatment, Laura felt tired. During the treatment she had restarted Prozac and she continued to be prescribed Prozac. The family's financial situation continued to worry her.<sup>521</sup>

**6.264** At a review appointment in April 2000, Laura was told that her blood test results remained encouraging, 'but that we still do not have enough knowledge about the natural history of hepatitis C to say with complete confidence how the disease may progress in the future'.<sup>522</sup> This uncertainty about the future was always 'in the back of [Laura's] mind'.<sup>523</sup> Despite this, Laura tried to bring some sort of normality back to family life. In particular, feeling more energetic than she had done previously, she made an effort to do more activities with their children.<sup>524</sup>

### *The period since Laura's treatment with Interferon and Ribavirin*

**6.265** In 2000, Laura was diagnosed with breast cancer. She was treated for this at the Western General Hospital, Edinburgh. Laura was told that the cause of the cancer was unclear. She had no family history of this type of cancer. She was told that hormones and stress could have contributed to this diagnosis. Laura had concerns that the treatment for

---

<sup>517</sup> Day 79, page 51

<sup>519</sup> Ibid, page 43

<sup>520</sup> Ibid, pages 53–54

<sup>521</sup> Ibid, page 55

<sup>522</sup> Ibid, page 57; Excerpts from the medical records recovered in respect of Laura

<sup>523</sup> Day 79, page 57

<sup>524</sup> Ibid, page 57

Hepatitis C, and the stress she suffered, contributed to her diagnosis with breast cancer. She mentioned this at one of her appointments at the hospital and nobody said that this could not have contributed to it. This concerned her.<sup>525</sup>

**6.266** Laura was treated with a mastectomy, reconstructive surgery, chemotherapy and five years of hormone drug treatment. Those treating Laura were aware of her previous diagnosis with Hepatitis C and the virus was taken account of when treatments for the breast cancer were being considered. Laura's Oncology Consultant discussed matters with Professor Ludlam's Clinical Assistant and with Professor Hayes. She was told that despite Laura being Hepatitis C PCR negative, Laura should still be considered 'at risk during surgical procedure'.<sup>526</sup> Professor Hayes was also asked whether chemotherapy would reactivate her Hepatitis C. His response to this was that as Laura was PCR-negative:

[W]e would hope that she is cured of hepatitis C and therefore if the virus has gone she would not reactivate even if this is immunosuppressed. However, of course a certain number of people do relapse after treatment and it is possible, although we cannot detect it that she might still be harbouring hepatitis C somewhere.<sup>527</sup>

He suggested that Laura undergo a PCR test every two to three months. Laura was unaware that these matters were being discussed by her doctors. Although there was a note in Laura's medical records of her concern about the impact of the chemotherapy treatment on the Hepatitis C virus, Laura does not remember being overly anxious about this.<sup>528</sup>

**6.267** Laura completed her chemotherapy treatment in about April 2001. It had no effect on her liver function. At a review appointment at the Haemophilia Clinic on 30 April, Laura was noted to be keen to have a quantitative Hepatitis C PCR test. Laura was advised by letter dated 18 June that year that this test, and her ALT, was normal. Laura's treatment for breast cancer was successful.<sup>529</sup>

**6.268** Laura continued to attend the Haemophilia Clinic for review annually. After the doctors there had taken the advice of Professor Hayes, Laura was discharged from this clinic in November 2006.<sup>530</sup>

**6.269** More recently Laura has developed inflammatory bowel disease. Once again, while being treated in hospital, 'there was a lot of talk in hospital about the fact I have had Hepatitis C'.<sup>531</sup> She has been treated for her bowel disease with steroids. She was unable to take another medication for this as there was concern about the effect it might have on Laura's immune system, due to her previous diagnosis with Hepatitis C.<sup>532</sup>

<sup>531</sup> Ibid

<sup>532</sup> Ibid, pages 64–65

### *Specific impacts of Laura's infection with Hepatitis C*

**6.270** Laura believes that one consequence of her infection with Hepatitis C is that her children are more protective of her. At the time she took her treatment for the virus, she was very careful to hide it from the children. She hid the needles she used to inject herself. They were unaware that she was taking treatment. However, she considers that her son was old enough to sense that his mother was unwell and that 'things weren't quite right'.<sup>533</sup> He is now very protective of her. As a toddler, her daughter was loath to let her mother out of her sight and she is much more insecure than Laura expected her to be.<sup>534</sup>

**6.271** Laura considers that her infection with Hepatitis C had the greatest effect on her relationship with her husband. Although Laura and her husband tried to keep the strain in their relationship from the children, Laura believes that the children sensed it anyway and 'were inevitably going to be affected by it'.<sup>535</sup>

**6.272** As detailed in paragraphs 6.257 to 6.259 above, Laura's diagnosis with Hepatitis C, and the consequences of it, had a significant and detrimental impact on her relationship with her husband for a number of years. In about 2008, Laura and her husband attended a series of couple counselling sessions: 'our problems reached a point where it was either a case of we gave up on our relationship or we went for counselling'.<sup>536</sup> She stated that neither of them was inclined to give up too easily which she believes is a reason why they remained together. Another reason was that, for a time, they could not afford to separate due to the debts they had incurred. Initially Laura's husband found it difficult to accept the idea of counselling. During the counselling sessions Laura and her husband talked a lot about how they both felt 'during ... the Hepatitis C period'.<sup>537</sup> Laura stated:

[I] learned a lot about how he felt and I think that helped me to sort of accept that it wasn't all his fault. And I knew deep down it wasn't but I think his way of handling the situation also contributed to the problems and we both ... faced up to things and our relationship is much, much better now and back on track. It has just taken a long time. That has been a lot of years before we reached that point.<sup>538</sup>

**6.273** Laura feels that it would certainly have helped her husband to have been offered counselling sooner, perhaps when she received counselling from a psychologist, but this was not offered to him.<sup>539</sup>

**6.274** Some of the financial impacts of Laura's infection with Hepatitis C have already been stated in paragraph 6.249 above. As a result of the debts the family incurred when Laura had to wind up her business, the family acquired a bad credit rating. They had planned to move from their two-bedroom flat to a house to give their children more space, but this was delayed by about five years. Due to their bad credit history, they found it difficult to obtain a mortgage. A local broker assisted them with this but the mortgage they obtained had a slightly higher interest rate than the average. Laura was unable to obtain new life assurance to cover the mortgage. She had a policy which she had acquired prior to her diagnosis with

---

<sup>533</sup> Ibid, page 66

<sup>534</sup> Ibid

<sup>535</sup> Ibid, page 67

<sup>536</sup> Ibid

<sup>537</sup> Ibid, page 67

<sup>538</sup> Ibid, page 68

<sup>539</sup> Ibid, page 69

Hepatitis C. Furthermore, she was unable to afford the premiums quoted to her for income protection insurance, due to her infection with Hepatitis C, and so her husband obtained this and she did not. In addition, Laura has incurred inflated travel insurance premiums due to her infection with Hepatitis C. She has also incurred travel expenses attending regular appointments at the hospital and prescription charges. Laura and her husband remain in debt: 'We have never really managed to get back on track ...'.<sup>540</sup>

**6.275** As a result of the stigma attached to the Hepatitis C virus, Laura still has not told many people that she had it. Her current employers do not know that she had the virus. She found it difficult to take time off work to attend hospital appointments during her treatment with Interferon and Ribavirin but her employers were understanding and did not ask about the reason for the appointments.<sup>541</sup>

**6.276** On one occasion, Laura had to attend hospital for a tooth extraction. Although she was one of the first patients to arrive for the procedure that day, she was kept waiting until the end of the day. When she enquired why she was having to wait so long she was told by a nurse that it was due to her having Hepatitis C. The operating list was rearranged so that Laura was last as she was deemed a risk in the theatre. She understood that the theatre required to be disinfected after her procedure. She was shocked and upset by this. In addition, Laura was given a paper gown although everyone else that day wore a cloth one. This made her feel as if she had a 'horrible disease' and that nobody wanted to come near her.<sup>542</sup>

**6.277** In describing the effects of her infection with Hepatitis C on her and her family, Laura said, 'This whole period in my life was a nightmare for me and my whole family. It has taken many years to recover from most of the effects, and some effects we will never recover from'.<sup>543</sup>

## Anne

**6.278** At the time of giving evidence, Anne was 57 years old. She lives in Ayrshire and works as an administrator.<sup>544</sup>

### *Anne's blood transfusion*

**6.279** Anne contracted Hepatitis C, Genotype 2b, from a blood transfusion she received in a local hospital in January 1986. At that time Anne was 31 years old. She was admitted to hospital for a myomectomy (surgical removal of fibroids) and as a result of this procedure, Anne required a blood transfusion. Anne is uncertain how many units of blood she received, but she thinks that it was more than three units. This is the only blood transfusion which Anne has ever received. Anne was a blood donor prior to receiving this blood transfusion but, due to low haemoglobin levels, did not donate afterwards.<sup>545</sup>

### *Anne's diagnosis with Hepatitis C*

**6.280** In 1995 Anne's sister, who provided a statement to the Inquiry, had a routine appointment with her GP. This GP was also Anne's GP. He asked Anne's sister to ask Anne to make an appointment to see him but did not explain why. Anne's GP had been advised by

---

<sup>540</sup> Ibid, pages 69–72

<sup>541</sup> Ibid, pages 72–73; Laura's Witness Statement

<sup>542</sup> Ibid, pages 73–74

<sup>543</sup> Ibid, page 74; Laura's Witness Statement

<sup>544</sup> Day 79, page 77

<sup>545</sup> Ibid, pages 77–78

the Scottish National Blood Transfusion Service (SNBTS), by letter dated 16 October 1995, that Anne had been transfused with 'a presumed hepatitis C positive blood component' in January 1986.

**6.281** Anne's sister conveyed this request to Anne. Anne considers that this was 'a very strange way' for her GP to initiate 'such important contact with [her]'.<sup>546</sup> Anne made an appointment to see him on 24 November. At the time of this appointment, Anne was 41 years old. She did not feel unwell. Anne's memory of exactly what happened at the appointments with her GP around this time is understandably hazy in view of both the time which has elapsed since, and the impact of the news she received. Having considered her medical records as well as Anne's evidence, it appears that at the appointment on 24 November, Anne's GP told her that it was likely that she had acquired Hepatitis C and a blood sample was taken to confirm this.<sup>547</sup> At the following appointment her GP confirmed her Hepatitis C diagnosis. Anne's GP gave her the impression that Hepatitis C was nothing to worry about. He said to her 'not to worry about it because it didn't really mean anything'.<sup>548</sup> Anne had never heard of Hepatitis C.<sup>549</sup> She did not receive any advice from him about the implications of a positive result. She did not receive any counselling or advice about her future health. Her liver was not discussed. All he told her was 'Don't drink, and tell your dentist'.<sup>550</sup> Anne believes that her GP did not realise the seriousness of the virus.<sup>551</sup>

**6.282** Despite her GP's assessment of her diagnosis, Anne realised it was something to be concerned about and she was worried about it: '[I]f you have a virus, it's obviously something'.<sup>552</sup> She made contact with the local hospital to try to obtain an explanation as to how she had become infected and what her prognosis was. Sometime in 1996 she met with a representative of the SNBTS and a hospital representative at the local hospital. She did not find the meeting helpful. She found the attitude of the hospital representative upsetting, although the doctor from the SNBTS was helpful.<sup>553</sup>

### *Anne's treatment for Hepatitis C*

**6.283** Anne's GP referred Anne to Dr Mills' Hepatitis Clinic at the Gartnavel General Hospital in Glasgow. On 12 March 1996 Anne attended her first appointment there. She was seen by a Senior Registrar. On examination Anne was found to look well and there were no signs of chronic liver disease. The doctor had a long talk with Anne about the implications of Hepatitis C infection. This included the prognosis for someone with Hepatitis C, the risks of liver disease, sexual transmission and treatment options; namely Interferon. Anne was 'gobsmacked' as this was the first time she understood the full implications of the virus. She was told that 'anything that was likely to happen would probably be about 20 years down the line'.<sup>554</sup> This worried her as she realised that she had already had the virus for about nine or ten years. The doctor suggested that Anne have a liver biopsy.<sup>555</sup>

<sup>553</sup> Ibid, pages 91–92

<sup>554</sup> Ibid, page 93

<sup>555</sup> Ibid, pages 93–94; Excerpts from the medical records recovered in respect of Anne

**6.284** Anne felt shocked after this appointment. She returned home and relayed the information she had been given to her mother and sister. They did not know anything about the virus either, and they all started to try to find out more about it.<sup>556</sup>

**6.285** On 26 June 1996 Anne underwent an ultrasound-guided liver biopsy. She found this a very invasive and painful procedure: 'I am not a coward but I found this very hard'.<sup>557</sup> The biopsy revealed 'a mild hepatitis consistent with Hepatitis C'.<sup>558</sup> It was suggested to Anne that she start treatment with Interferon. Anne knew that she had to take treatment for the virus. At the time she was experiencing flu-like symptoms.<sup>559</sup>

**6.286** Since her diagnosis with Hepatitis C she has had five liver biopsies. Anne subsequently became aware of the risks associated with liver biopsies and believed that this 'amplifies the actual and real risks' which she has been subjected to as a result of the virus.<sup>560</sup>

### *Anne's treatment with Interferon*

**6.287** Anne started Interferon treatment on 29 January 1997. Prior to starting this treatment Anne was taught how to inject herself. She was warned about the side-effects of the treatment. She was warned that she might experience flu-like symptoms, hair loss, tiredness, depression, dry mouth and bone marrow suppression.<sup>561</sup> Anne had to inject herself three times a week.<sup>562</sup> It was noted in Anne's medical records two weeks after she started treatment that on the first day of treatment she experienced 'slight flu symptoms with a headache persisting all next day. Cold during the night.'<sup>563</sup> It was noted after Anne had completed four weeks of treatment that she was suffering from 'slight flu symptoms, easily coped with. Cramp in legs during night'.<sup>564</sup> After eight weeks of treatment the leg cramps had settled, but the headaches and slight flu symptoms persisted. These symptoms were worse the day after Anne injected herself and settled with paracetamol. Twelve weeks after starting treatment Anne continued to suffer from headaches, and was tired especially after injections. She also suffered from hair loss. At this time Anne was noted to be Hepatitis C PCR-negative with a reduction in serum transaminases to normal. At this time Anne was told that she had cleared the virus although she was also told that the virus could 'hide and come back again'.<sup>565</sup> Unfortunately, after 24 weeks of treatment, Anne was once again PCR-positive with an elevated AST. At this time Anne was also found to have hypothyroidism, a known side effect of Interferon treatment. Anne started treatment with thyroxine, which she continues to take now.<sup>566</sup> Anne's dose of Interferon was increased at this time. After a further 12 weeks of treatment at this level, Anne's dose of Interferon was reduced for the final 12 weeks of treatment. She stopped taking treatment 48 weeks after starting it.<sup>567</sup>

<sup>564</sup> Ibid

<sup>565</sup> Ibid, page 99

<sup>566</sup> Ibid, page 100

<sup>567</sup> Ibid, pages 100–101

**6.288** Anne gained about half a stone in weight during the Interferon treatment.<sup>568</sup> She managed to keep working throughout the course of treatment. She had to attend the hospital for appointments and initially these were once a week to collect the Interferon to bring home and keep in her fridge. She used flexi-time to allow her to do this. This added to the pressure of the treatment on her.<sup>569</sup>

**6.289** On 17 December 1997 Anne underwent a further liver biopsy. The features of this biopsy were similar to the previous one.<sup>570</sup> Anne was told that the Interferon treatment had not been successful and that there was no real change in the state of her liver. She was told that she would attend the hospital annually and that 'probably there would be treatment in the future, but obviously that would be a few years down the line'.<sup>571</sup> Anne was glad that the treatment was over. The side-effects of it persisted for a further few months.

**6.290** At a review at Dr Mills' clinic in December 1999, it was noted that Anne remained well, apart from 'some slight discomfort in the muscles of her upper legs'.<sup>572</sup> Dr Mills discussed possible improvement in treatment for Hepatitis C but noted in a letter to Anne's GP that 'It seems likely that it will be at least three years away until the next generation of treatment becomes available for her'.<sup>573</sup>

**6.291** Anne continued to attend Dr Mills' clinic annually for review. In July 2002 Anne was noted to be in 'reasonably good health' although she was complaining of having more flu-like symptoms than previously, having headaches in the morning and feeling tired each day at about three o'clock. The possibility of Anne being treated again with combination Pegylated Interferon and Ribavirin was discussed, but Anne decided to postpone this treatment. She reached this decision as, having found the treatment so invasive the first time, she wished to carry on for a further year without it and to keep working.<sup>574</sup>

**6.292** At the review the following year, Anne was noted to be remaining well, although she was occasionally tired and went to bed an hour and a half earlier than usual. Once again, she decided to postpone treatment for the same reasons as before. She knew that at some point she would have to undergo further treatment but she still wanted to put it off.<sup>575</sup>

**6.293** In October 2004 Anne underwent a further liver biopsy to aid the decision as to whether she required to make a further attempt at treatment. Once again, this showed similar appearances to the previous biopsies and no evidence of progression. Her liver function tests remained normal and she had no particular symptoms of the virus.<sup>576</sup> On the basis of this, once again, Anne decided to postpone treatment. She continued to attend for annual review.<sup>577</sup>

**6.294** Gradually Anne began to suffer more symptoms of Hepatitis C. She began to suffer flu-like aches and pains, constant tiredness, intermittent insomnia and alopecia. At

<sup>577</sup> Day 79, page 108

a clinic appointment in December 2008, Anne stated that she had noticed that her fatigue had become more pronounced and as a result she was no longer able to attend the gym. Prior to this Anne had for many years gone to aerobic classes at the gym. As she stated, it was 'a big deal when I had to stop that'.<sup>578</sup> An ultrasound scan of Anne's abdomen on 14 April 2009<sup>579</sup> revealed that Anne's liver was mildly enlarged. Anne was told this but was not told what it meant. Anne was also told that there was no tumour on the liver.

**6.295** As a result of the impact of her symptoms on her daily life, Anne felt that the time had come to start considering treatment for the virus. She considered that starting treatment was 'a big commitment' which impacted on both her working and private lives.<sup>580</sup> One factor Anne took account of in deciding when to start treatment was the impact of this on her job. Anne was warned by management at work of the risk of potential redundancy. As a result of this she decided to put off the treatment as long as possible so as not to jeopardise her employment.<sup>581</sup> The threat of redundancy remains to this day due to changes in Anne's area of work.<sup>582</sup> A further difficulty for Anne in receiving treatment was that, although she could drive, she did not drive to the hospital due to the effects of the treatment, especially the fatigue. This meant that she was required to take two trains there, and back, amounting to a three hour return journey. Anne stated that she is a private person and would rather not have told her employers that she was undergoing the treatment. However, due to the length of time involved in attending clinics and regular reviews, she felt that she had to tell her employer's Human Resources manager about the treatment.<sup>583</sup>

#### *Anne's treatment with Pegylated Interferon and Ribavirin*

**6.296** On 16 September 2009 Anne started a six-month course of Pegylated Interferon and Ribavirin. This involved Anne injecting herself with Interferon and taking Ribavirin orally in tablet form. Anne deliberately arranged to start this treatment on the Wednesday before a holiday weekend so that it would not impact on her work. She took annual leave on the Thursday of that week as she knew from her previous treatment that she would experience bad side-effects. In fact, Anne found the side-effects worse than she had remembered. She suffered from very bad flu-like symptoms and had to spend the rest of the holiday weekend indoors. She felt that her holiday weekend 'was completely wasted'.<sup>584</sup>

**6.297** Anne developed a routine during the course of her treatment whereby she took her Interferon injection on a Wednesday evening. In order to allow herself more time to recover from the injection and to enable her to cope with her 45-minute commute to work, Anne obtained permission from her employer to start work three and half hours late on a Thursday, and finish early on a Friday. On a Thursday she did not take any breaks and worked right through the day. She found that reducing her hours helped her manage to continue working while taking the treatment. She had to attend regular clinic appointments during the course of the treatment, initially fortnightly and then monthly, and so missed further time at work. Her reduced working hours and her absences due to clinic appointments did not affect her pay.<sup>585</sup>

<sup>584</sup> Day 79, pages 112–113

<sup>585</sup> Ibid, pages 113–114

**6.298** This second course of treatment with Interferon and Ribavirin affected Anne greatly. She suffered both physical and psychological symptoms which she described as 'intense'.<sup>586</sup> With regard to the physical effects, she had continuous flu-like symptoms. During the first three weeks of the treatment, she took no fewer than six paracetamol tablets daily and thereafter took paracetamol regularly. She described some of the other side effects as follows:

My temperature fluctuated. I felt cold and clammy. I was shivery. I felt hot. I had a dry mouth. I produced less saliva due to interferon treatment. I had dry skin and suffered alopecia. I saw my hair on the pillow and in the shower. I suffered from poor concentration. In the first two months of treatment my concentration was exceptionally low. On a scale of one to ten, it was zero to one only. Towards the end of the treatment I was living with concentration levels at, say, five out of ten. My immunity to fighting infection was compromised. I had a non-productive dry cough for the first six weeks of treatment followed by a serious chest infection which lasted four weeks requiring antibiotics. My appetite was suppressed. I did not feel hungry. I had to force myself to eat. In the early weeks of Interferon treatment I skipped many meals and ate tiny portions. I was unable to eat starchy foods such as potatoes.<sup>587</sup>

**6.299** Initially, Anne lost weight during the treatment but, due to a craving she developed for ice cream, she regained this prior to finishing the treatment. During the treatment Anne never had a good night's sleep. She often had vivid nightmares which caused her to wake early, about 4 am, and remain awake for the rest of the night. She used to take a nap during the day which she never did before starting treatment. Anne's stamina was reduced. She estimated that, on a scale of one to ten, her stamina was only three. If she went shopping with her sisters, she had to sit down for 20-minute spells at least three times during the course of an outing. In September 2009, she had to stop swimming which she had previously enjoyed.<sup>588</sup>

**6.300** In addition to these physical symptoms, as a result of the treatment, Anne was diagnosed with symptoms consistent with Interferon-induced mood disorder and associated insomnia. Although she did not notice it at the time, her mood and personality began to alter as the treatment progressed. She became irritable and anxious. She suffered from panic attacks. She experienced episodes when she lost her self-control. At times she shouted, 'Get out of here' or 'Please go away' to people.<sup>589</sup> She spent one weekend in bed communicating with no one. She experienced a form of claustrophobia as she was unable to cope if she found her immediate doorway or exit being blocked. In such situations she had to pinch herself to try to make these feelings subside. She developed a strategy of taking herself for a walk to calm down and used this many times both at home and at work. At one point, Anne told her sister that she could understand how someone might be driven to suicide. Now that her mental state has improved, Anne cannot believe that she said this.<sup>590</sup>

<sup>588</sup> Day 79, pages 122–123

<sup>589</sup> Ibid, page 115

<sup>590</sup> Ibid, pages 114–115 and 118

**6.301** Anne's sister provided a statement to the Inquiry.<sup>591</sup> It was provided eight months after Anne commenced this second course of treatment and so the events she described in her statement were recent. Anne's sister was on holiday at the time Anne started the drug regime. Before she left, Anne was very tense about starting the treatment. On her return from holiday Anne's sister immediately noticed changes in Anne's personality and became very worried about her:

Anne was irritable and narky. I could not say anything to her without her reacting in an extremely confrontational manner. She was twisted and volatile and really hard to live with. It was a very difficult time. [Anne] had episodes of daily anger .... [Anne's] behaviour was really destructive. I worried about how I would speak to her because she became hypersensitive. She became a 'monster'. In a rage she would behave with eyes flaring and voice blaring. I became really worried and had to keep a daily eye and check on how things were .... [Anne] was out of control, snapping and being like a huffy, moody teenager. My son who is a loving nephew aged 20 years old avoided [Anne] for months ....<sup>592</sup>

**6.302** The description Anne's sister gave of Anne during the treatment was hard to reconcile with the person who appeared in the witness box at the Inquiry hearings. This highlighted the extreme psychological effect the Interferon had on her. Anne's sister described the change in her sister in September and October 2009 as 'very frightening'. Anne's sister stated:

The Interferon treatment was horrendous for [Anne]. The side effects of the drugs have placed the entire family under pressure. We could not possibly have envisaged the violent effects of this medication. It is upsetting today to recall all of this.<sup>593</sup>

**6.303** Anne's behaviour had a significant impact on her 85-year-old mother with whom she lived. Anne's mother felt threatened and vulnerable living with Anne during this period. On one occasion Anne's other sister witnessed 'a huge volatile row' between Anne and her mother and had to intervene to protect their mother. Anne is aware that her mother bore the brunt of living with her, the symptoms she suffered from Hepatitis C and the Interferon and Ribavirin treatment. Anne's sister stated that she knows that Anne's behaviour has 'deeply upset' Anne herself.<sup>594</sup>

**6.304** On one occasion Anne was so consumed with 'uncontrollable and involuntary anger' that, to prevent herself kicking her mother, Anne kicked a door.<sup>595</sup> She was so ashamed of her actions that she 'jumped in [her] car and took a long drive in tears'.<sup>596</sup> Shortly after this episode Anne attended a review appointment at the hospital at which she was asked to complete a questionnaire on how she was feeling. Anne reacted to this by having 'a mini breakdown' and she told the nurse how bad she felt. Anne felt that the nurse understood her problems and told her that she considers the psychological side-effects of Interferon very seriously. This was the first time Anne connected how she was feeling to Interferon, although she had been warned that the treatment might affect her

mood.<sup>597</sup> The nurse suggested two options to Anne – the first being to attend her GP and to ask for anti-depressant treatment, the second being to speak with the psychiatrist at the Brownlee Centre, Gartnavel Hospital, Glasgow.

**6.305** Anne decided to follow the second option and so, in October 2009, attended an appointment with a psychiatrist at the Gartnavel General Hospital. The psychiatrist considered that Anne's clinical presentation with regard to her mood and sleep disturbance was entirely in keeping with a diagnosis of Interferon-induced mood disorder and associated insomnia. Anne was prescribed anti-depressant therapy. It took three weeks for this medicine to improve Anne's symptoms. Anne attended a number of appointments with the psychiatrist. He noted that Anne continued to experience intermittent bouts of anxiety until the completion of her treatment in March 2010. In the last two to three weeks of the treatment her sleep pattern again deteriorated, with nocturnal disturbance secondary to disturbing dreams.<sup>598</sup> The psychiatrist suggested that Anne stop taking the antidepressant medication at the end of her treatment, but the nurse attached to the Hepatitis C clinic considered that it was too soon for Anne to stop it. Anne continues to take this medication and is 'not too anxious to come off it'.<sup>599</sup>

**6.306** To her credit, despite the severity of the side-effects of the Interferon and Ribavirin treatment, Anne continued to work during it.<sup>600</sup> Anne had been told by the Specialist Nurse that there was an 80% success rate of the treatment in those people, like her, who had Genotype 2 of the virus. Anne was 'exceptionally hopeful' that the treatment would be successful. She nearly gave up taking the treatment, due to the effect of it on her mood, but the antidepressant medication enabled her to continue with it.<sup>601</sup> One month after she started the treatment, blood tests revealed that Anne was Hepatitis C negative.<sup>602</sup> However, a blood test taken when Anne finished the treatment in March 2010 revealed that she was Hepatitis C positive. Anne discovered on 30 March 2010 that the treatment had failed. Understandably she was very upset. The Specialist Nurse was shocked that the virus was detectable so soon after she finished treatment. A further blood test in September that year confirmed this positive result. Anne has been classed as 'a non-responder to combination anti-viral therapy'.<sup>603</sup>

**6.307** Anne's sister described in her statement how upset the family was that the treatment did not work:

[N]o one envisaged the treatment failing so quickly. My sister and mother are very upset. My mother continues to worry about [Anne]. Her life has been so challenging. We have all been affected with the effects of Hepatitis C in some way.<sup>604</sup>

Anne too realises that her mother worries about her. She added that her mother has worried about her for 25 years and 'that is most unfortunate'.<sup>605</sup>

<sup>604</sup> Anne's sister's Witness Statement

<sup>605</sup> Anne's sister's Witness Statement

### *Anne's present symptoms*

**6.308** For a couple of months after the treatment finished Anne continued to suffer from some anxiety and panic attacks, but these have now resolved. Anne continues to suffer from flu-like symptoms and aches and pains. Her stamina remains poor, and she has been unable to return to her hobbies of aerobics and swimming. She continues to suffer from fatigue and goes to bed earlier than before. According to Anne's sister's statement, 'She is ill just now. She tires very easily. She cannot even cope physically with going shopping and has to sit down every hour for a long rest'.<sup>606</sup>

**6.309** Anne now attends the liver clinic annually for monitoring.<sup>607</sup> With regard to her prospects Anne states, 'I do not know what my future holds for me. My future is very uncertain'.<sup>608</sup> Anne understands that there may be more treatment for Hepatitis C in a few years but she is unaware what that treatment may be.<sup>609</sup>

### *Specific impacts of Anne's infection with Hepatitis C*

**6.310** Anne described the impacts of her infection with Hepatitis C as follows:

[It] has had a profound impact upon my life. This has reduced my life opportunity in terms of maintaining personal relationships, obtaining employment chances and the subsequent economic disadvantage suffered by me as a result. In my opinion this is why I remained single and did not progress or encourage potential marriage options. I was a young woman when this happened to me. I did not encourage any long-term relationships. You have to draw the risk of transmission of this virus to someone's attention right away. My confidence to do so was non-existent. I have missed out with the opportunity of potentially raising a family of my own.<sup>610</sup>

**6.311** Her infection with Hepatitis C has exacerbated Anne's anxiety about her work situation. Anne has worries about how she would be able to obtain a new job in light of her condition and, for example, whether she would need to declare to any new employer that she had Hepatitis C. 'My age together with Hepatitis C will rule out many employment options available to me.'<sup>611</sup> At present her work situation has settled but, as she stated, the threat of redundancy 'raises its head every now and again ...'.<sup>612</sup>

**6.312** With regard to financial consequences of her infection with Hepatitis C, Anne has a mortgage but she did not have to disclose her diagnosis to her mortgage provider. She worries about being unable to pay the mortgage were she to lose her present job. She has no life assurance as she does not wish to discuss her diagnosis with potential insurers. She has obtained travel insurance, but has not divulged the fact that she has Hepatitis C to the insurers. She has incurred travel expenses attending many clinic and other appointments at the hospital. She received the first Skipton Fund payment in 2004. When her GP signed the Skipton Fund application form for her, he remarked that only three of his patients had Hepatitis C and they were all drug users. It appeared to Anne that he did not differentiate her status, as having acquired it through no fault of her own, from theirs.<sup>613</sup>

<sup>612</sup> Day 79, page 131

<sup>613</sup> *Ibid*, pages 133–134; Anne's Witness Statement

**6.313** Anne is concerned about the stigma attached to the Hepatitis C virus. She likes to keep such a personal matter to herself and is keen to preserve her privacy. She lives in a small community. She has told very few people about her diagnosis.<sup>614</sup>

### **Alex**

**6.314** Alex is presently in his mid-20s.<sup>615</sup>

**6.315** Alex has severe Haemophilia A and was infected with Hepatitis C, Genotype 1a, from his treatment with blood products.<sup>616</sup> He was infected with the virus when he was very young and he was assisted in the evidence he provided to the Inquiry by his father, who also provided the Inquiry with a witness statement,<sup>617</sup> and by referring to reports and notes which were kept by his late mother.

### *Alex's diagnosis with haemophilia and his treatment for this*

**6.316** Alex is the youngest of four children. He has two brothers and one sister. As a child Alex's family lived in a remote part of Scotland. In October 1986, when Alex was about six months old, he developed a swollen right thigh and was distressed. His GP referred him to a local hospital. Initially it was thought that Alex had developed osteomyelitis (bone infection) and he was treated with medication for this. On 22 October Alex was referred to a regional hospital. There, a coagulation screen revealed that Alex had Haemophilia A. It was noted that this appeared to be the result of a spontaneous mutation as the Factor VIII levels in Alex's mother, and in his two brothers, were normal. As there was no family history of haemophilia, Alex's parents had no knowledge or experience of haemophilia. The discharge document from Alex's admission to the regional hospital states that '[Alex] was given an infusion of cryoprecipitate before going home so that his parents could see what was involved, although he did not have any bleeding disturbances at that time'.<sup>618</sup> Alex's father remembers this first treatment very well, although until he saw the discharge letter recently, he thought that Alex's first treatment was with Factor VIII concentrate. Alex's father stated that nothing was discussed with him or his late wife about the treatment Alex was given. He remembers a doctor coming into the ward to see them and saying that they needed to treat Alex with Factor VIII as this was all they could do for haemophilia. At that time Alex's parents did not know what haemophilia was. The doctor said that they would give him a dose of Factor VIII, and that Alex would probably need to take Factor VIII for the rest of his life.<sup>619</sup> It is possible that this is how the doctor referred to the cryoprecipitate since it contains Factor VIII.

**6.317** Alex's parents clearly found this first admission to the regional hospital a traumatic experience. It took eight days for Alex to be diagnosed with haemophilia.<sup>620</sup> During this period Alex gave a number of blood samples for tests. Each time he was taken away from his parents and they would hear him screaming while the sample was being taken. He returned to them with bruises on his arms.<sup>621</sup>

<sup>619</sup> Day 81, pages 8–10

<sup>620</sup> Alex's father's Witness Statement

<sup>621</sup> Day 81, pages 11–12

**6.318** In January 1987, Alex developed swelling of his left thigh. Initially he was admitted to a local hospital where he was treated with three doses of Factor VIII concentrate. The swelling did not improve, and so the local hospital decided to refer him to a larger hospital for further review. At Alex's parents request this referral was made to the Royal Hospital for Sick Children (Yorkhill) in Glasgow instead of the regional hospital.<sup>622</sup> Alex was admitted to Yorkhill Hospital on 22 January 1987. He was treated daily with cryoprecipitate. This resolved the bleed and Alex was discharged home on 28 January. During his admission Alex's Factor VIII level was checked again, and was found to be less than 1%, indicating severe haemophilia.<sup>623</sup> Alex's mother, who accompanied him during this admission, was provided with further information about haemophilia and was introduced to parents of older children with the condition.

**6.319** In March 1987 Alex fell and cut his tongue on his teeth. Initially he was treated at home with Factor VIII, but this failed to stop the bleed. So he was admitted to Yorkhill where he was treated with two bags of cryoprecipitate and then tranexamic acid (a drug used in the control of bleeding). It was noted in the discharge letter from this admission that Alex's parents were under considerable stress. Alex's father explained in his evidence to the Inquiry that their stress was due to Alex's diagnosis with haemophilia, and the fact that they lived in such an isolated place. 'We had nobody in our area with the same problem and there was nobody we could discuss it with'.<sup>624</sup> With the help of their GP Alex's parents found out about two other families in their local area who had experience of mild haemophilia. One was an 80-year-old man, and the other was a family who had lost their son before Alex was born. They did not wish to discuss haemophilia with Alex's parents. According to Alex's father there was stigma about haemophilia, which is likely to have been due to the publicity surrounding HIV at that time.<sup>625</sup>

**6.320** Alex usually attended his GP if he had a bleed. He attended Yorkhill for review appointments every three or four months. One of his parents accompanied Alex to these appointments, while the other parent stayed at home to look after their other children. Each appointment usually involved a round trip of two days, and staying overnight in Glasgow. Alex did not enjoy staying in the city. At one point Alex's parents considered moving to Glasgow to be nearer Yorkhill.<sup>626</sup>

**6.321** At each of Alex's review appointments he underwent a blood test. Alex's parents were told that these tests were to check his factor levels and his liver function. At some point Alex's parents were told that he was being tested for 'non-A, non-B' but they did not know what it was.<sup>627</sup> It was not explained to them. Alex's father recalled asking on one occasion what non-A, non-B was and he was told 'It is just a test that we do'.<sup>628</sup> He knew that everyone with haemophilia was being tested for this. Alex's parents were not told the results of these tests. In April 1991 Alex underwent an abdominal ultrasound, the results of which were normal.<sup>629</sup>

<sup>629</sup> *Ibid*, page 37

**6.322** Alex started prophylactic treatment with Factor VIII concentrate in about October 1990 when he was four years old. It was usually Alex's mother who gave him the injections of Factor VIII, but if she was unable to access a vein, or it was 'a struggle', the GP would administer the treatment. Alex hated the injections: 'I understood why I had to get them but it just wasn't very nice having to have a needle stuck into your arm'.<sup>630</sup> This home treatment was obviously distressing for Alex and his family, in particular his mother. Alex continued to attend Yorkhill every three months for monitoring, which included blood tests.<sup>631</sup> These blood tests included liver function tests. It seems that, at this time, Alex's parents were unaware that his liver function was being monitored.<sup>632</sup>

**6.323** Alex started school in August 1991. He suffered recurrent bleeds once or twice a week. These were usually in his ankles and knees. When they occurred Alex was unable to weight bear for several days, and had to be carried everywhere by his mother. As a result of these bleeds Alex missed a considerable amount of schooling.<sup>633</sup> Alex was provided with a wheelchair to use when he had a bleed. This was used both at home and at school. Alex's school installed stair lifts to allow Alex to access the upstairs classrooms. Alex hated his wheelchair: 'it wasn't very cool to go to school in a wheelchair ... I would have to get pushed around as well and it wasn't very pleasant'.<sup>634</sup>

### *Alex's diagnosis with Hepatitis C*

**6.324** Alex's father was unsure when he and his wife discovered that Alex had acquired Hepatitis C. He thinks that it may have been roughly a year before Alex started treatment with Interferon: he started this treatment in April 1994.<sup>635</sup> He remembers his wife returning from one of Alex's review appointments in Glasgow, and relaying the news to him that Alex had Hepatitis C. His wife was very upset and so was he. They did not know what Hepatitis C was, and Alex's father stated that no explanation about the virus was given to his wife at that time. They eventually discussed it with Alex's GP who was very good to the family over the years. He explained to Alex's parents 'what Hepatitis C meant, what the implications were, the long-term and it wasn't nice'.<sup>636</sup> Alex's parents were not given any advice on how, and if, to tell Alex of his diagnosis. They were not offered counselling. None of the family was offered testing for the virus.<sup>637</sup>

**6.325** Alex was about seven years old at the time his father believes they found out he had Hepatitis C. Alex does not remember being told that he had Hepatitis C: 'there was never one point where I was sat down and told, it was always just kind of there. I had haemophilia, I had Hepatitis C'.<sup>638</sup> Alex remembers asking his mother on the way to one of his review appointments what Hepatitis C was, and why he needed treatment for it. She told him that it was like a scar on his liver and that it was not very good that he had it.<sup>639</sup> Alex's parents only told a few members of his immediate family about his diagnosis with Hepatitis C: 'it has been kept very, very secret, within the family ...'.<sup>640</sup> They considered that there was already a stigma in respect of Alex having haemophilia and they did not wish to add to it. They believed that living in a small community made this worse.

### *Alex's treatment with Interferon*

**6.326** It appears that Interferon treatment was first discussed with Alex's mother in around 1993.<sup>641</sup> Alex and his father recalled that Alex's mother wished him to receive treatment for Hepatitis C, but she was apprehensive about the benefits and negatives of it.

**6.327** In January 1994, it was decided that Alex would start treatment with Interferon during the Easter holidays. Other than abnormal liver function test results, Alex was not displaying any symptoms of Hepatitis C although, looking back, now Alex feels that he suffered from bouts of tiredness, 'At the time ... I would never have associated the two but looking back, it did seem a bit strange that I would go a couple of days where ... I would just want to stay in bed. I guess for a young child I was quite tired'.<sup>642</sup> His parents were advised that the reason for starting the treatment was to delay the progression of the virus.<sup>643</sup> It was arranged that Alex would spend two weeks in Glasgow at the start of the treatment. Although Alex was supposed to be taking prophylactic treatment for his haemophilia, by this time he was not taking as much treatment as was prescribed. He was 'always quite resistant' to taking this treatment, and this was difficult for both Alex and his parents.<sup>644</sup> As the Interferon treatment was going to involve further injections, and in the hope that compliance with Interferon would be better, Professor Gibson, Consultant Haematologist, did not reinstate prophylactic treatment in January 1994.<sup>645</sup>

**6.328** Alex's parents felt that they were given 'sparse' information about the treatment by Yorkhill, so Alex's mother contacted the Haemophilia Society and enrolled to attend a symposium in Glasgow on Hepatitis in early 1994.

**6.329** On 30 March 1994 Alex underwent an abdominal ultrasound scan. The result of this revealed mild hepatomegaly (enlarged liver) but was otherwise normal.<sup>646</sup>

**6.330** On 1 April 1994, when he was eight years old, Alex started treatment with Interferon. His treatment with Interferon was given as part of a study entitled 'A Prospective Study of the Efficacy of Human Alfa [sic] Interferon in the Treatment of Chronic Liver Disease in Haemophilia'.<sup>647</sup> Over the months leading up to the trial, the implications of treatment for Alex and his family were discussed by Professor Gibson and the Haemophilia Nurse Specialist with Alex's mother, and a plan was made, including training, to deal with these. Alex's mother signed the consent form for this study after these discussions. The consent form records that the nature of the study and the side-effects of Interferon were explained to Alex's mother. Alex's father believes that his son was the youngest person in Scotland to become infected with Hepatitis C from blood products, and to receive Interferon treatment.<sup>648</sup>

**6.331** Alex's GP was obviously keen to support the family during the treatment. By letter dated 31 January 1994, Alex's GP wrote to Professor Gibson stating that he understood that Alex was due to start treatment with Interferon at the end of March. The GP asked Professor Gibson for 'any further information regarding Interferon treatment which you may be able to send me, and [I] would also appreciate copies of any information which

<sup>648</sup> Day 81, page 53

is provided to [Alex's parents] in order to facilitate any discussion with [them]'.<sup>649</sup> In her reply to this letter, dated 3 February, Professor Gibson wrote 'If the decision is taken to go ahead with Interferon therapy for [Alex] then I will keep you very informed of the risks and side effects'.<sup>650</sup> As stated above, Alex started this treatment on 1 April 1994. Professor Gibson did not keep Alex's GP informed about this treatment. On 16 August 1994 Alex's GP wrote to Professor Gibson that '[Alex's mother] tells me that he has been back to Yorkhill several times as his Interferon treatment continues. The last typed letter I have from yourself is dated 3 February 1994 and I wonder if it is possible to have an update on [Alex's] treatment since then?'.<sup>651</sup> In her reply to this letter dated 23 August, Professor Gibson stated that Alex tolerated the treatment 'very well' and that they had seen Alex at monthly intervals.<sup>652</sup> She noted that Alex had minimal local inflammation at the injection site but no other side-effects. She noted that there had been a little improvement in Alex's recent AST and ALT results but that they remained above the normal range.

**6.332** The injections of Interferon were administered to Alex by the community nurse at his house. When asked how he found taking the Interferon treatment Alex stated:

I hated it. I couldn't stand it. And I did feel sick from it. I just felt drained. [A]fter my first treatment I was really sick. I had ... extreme flu symptoms and hot sweats. It was never as bad as the first time but it was bad enough carrying on, and I also – because I hated going to the hospital so much, I hated having to go for my appointments – I never wanted to make a big deal about it in the hospital. I always tried to play down any illness I had.<sup>653</sup>

**6.333** The reason Alex did not stress these symptoms to the hospital was that he was worried that if he did, he would have to stay at the hospital: 'it was always such a horrible place to be'.<sup>654</sup> Alex remembers also feeling generally unwell. Alex's first treatment was around the time of his birthday. When he returned home after this he had a birthday party. Alex remembers that he did not wish to be around anyone. He did not wish to have to play with anyone and he stayed in his room. Alex's father stated that although the side-effects of the treatment had been explained to Alex's mother it was 'awful' when Alex received the treatment: 'I can't even go into the detail of what it was like. It was horrible, absolutely horrible to give it to a young child, these injections, the district nurse used to come in every day and every one of the family used to cringe to hear'.<sup>655</sup> When describing the effect of the Interferon treatment on Alex, his father stated '[I]t doesn't bear to think about what he went through'.<sup>656</sup>

**6.334** Alex's transaminase levels became normal within eight weeks of starting Interferon, and remained normal for the following month.<sup>657</sup> However, this improvement was transient, and by October 1994, six months after he had started the treatment, both his AST and ALT levels were elevated. Alex was consistently Hepatitis C PCR positive on all but one occasion in the first six months of his treatment; the one occasion apparently being of doubtful significance. As his liver function test results were abnormal at weeks 20 and

24, he fulfilled the criteria for trial failure and withdrawal from the trial. Alex's mother was informed at a review appointment in October 1994. She was understandably very disappointed by this, and after discussion with Professor Gibson it was agreed to continue Alex's treatment with Interferon for a further month. In fact, Alex's treatment continued until 17 February 1995. One of the reasons it was continued this long was that Alex's HCV RNA was negative in December 1994, but unfortunately it became apparent that this was another 'one off' result. At some point Alex's parents were told that with hindsight it might have been better had his treatment been stopped after six months.<sup>658</sup>

**6.335** Alex believes that he was 'quite happy' to stop the treatment as it meant that the injections stopped. At his age, the fact that the treatment had not worked did not mean much to him. He knew that having Hepatitis C was bad and that he needed to get rid of it.<sup>659</sup> He described his understanding about Hepatitis C as being 'a long period of discovery'.<sup>660</sup> Alex's father described the failure of the treatment with Interferon as '[V]ery, very disappointing, very hard to deal with, because there was no improvement whatsoever. He was still the same as he was before he started his interferon'.<sup>661</sup>

#### *Alex's condition after the Interferon treatment and the effect of both his haemophilia and Hepatitis C on his schooling*

**6.336** After his treatment with Interferon was stopped, Alex continued to attend Yorkhill Hospital for monitoring and annual ultrasound scans. His liver function test results remained mildly abnormal, but not sufficiently to cause concern. In 1996 there was some discussion among the doctors there about whether Alex would benefit from further treatment with Interferon at a higher dose, but these proved inconclusive.<sup>662</sup> In January 1997 Alex's mother, who was keen to pursue treatment options for the virus, was told by Professor Gibson that it was unlikely that Alex was eligible for the combined Interferon and Ribavirin trial which was about to start, as this was principally for patients who had become Hepatitis C negative during their treatment with Interferon, and had subsequently relapsed following its withdrawal. After his experience taking Interferon, Alex was not keen to take further treatment for Hepatitis C. In fact he continued to be reluctant to accept prophylactic treatment for his haemophilia.<sup>663</sup>

**6.337** In the late 1990s Alex started secondary school. His school was aware that he had haemophilia but did not know that he had Hepatitis C. When asked to describe how he found starting secondary school Alex stated:

I found it pretty hard. I found it quite hard to make friends. I never really had any best friends because I always felt like I had a tonne of secrets and baggage that I had to carry around .... It was hard enough to tell people that I had haemophilia let alone anything else. I felt quite withdrawn because of that, because I knew I had something to hide and I never really felt like I could open up or explain why I was going away every other month or what I was doing. I still do to this day. I am still quite closed.<sup>664</sup>

<sup>662</sup> Ibid, pages 67-69

<sup>663</sup> Ibid, pages 69-71

<sup>664</sup> Ibid, page 71

**6.338** Alex's bleeds changed at this time, and he found that he could go to school when he had a bleed although he probably should not have done so. He chose not to use his wheelchair: 'I didn't like being the disabled boy at school. I felt like I was labelled with that anyway because I was the only one with [haemophilia]'.<sup>665</sup> When Alex had a bleed, instead of going to school in a wheelchair, he often rested at home and then returned to school. He continued to miss a lot of school due to his bleeds. His target joints were developing and he had persistent bleeding into his right knee and his left ankle. In the event of Alex having a bleed at school, the school contacted Alex's parents either by the home telephone, or via a pager which the parents carried. They would then collect Alex and take him home for treatment there.<sup>666</sup> At one point Alex's school insisted that he wore a helmet to participate in gym lessons. Alex felt stigmatised by this and a doctor from Yorkhill Hospital wrote to the school advising that this was unnecessary.

**6.339** When Alex was younger and in primary school he did not think that having Hepatitis C was 'a big deal' and so he probably mentioned it to everyone. In secondary school Alex only told his best friend that he had the virus due to the stigma surrounding it. He felt isolated at school and ashamed of his condition.<sup>667</sup>

**6.340** In November 2000, when Alex was 14 years old, his Consultant Haematologist at Yorkhill sought the advice of Dr Morris, Consultant Gastroenterologist, on further treatment of Alex's Hepatitis C. Alex and his mother attended Dr Morris' clinic on 19 February 2001. At this appointment Dr Morris discussed the possible benefits of combined therapy with them and told them that it was their policy to consider liver biopsy in patients they intended to treat with this therapy. It was agreed that Alex and his mother would consider the pros and cons of further therapy and the potential risks of liver biopsy, before returning to the clinic in three months.<sup>668</sup> At this time Alex did not want a liver biopsy and was not keen on treatment:

At that time I didn't want [a liver biopsy]. I didn't see the point. I didn't feel like I had any main symptoms from it. To be honest, I just kind of ignored it. I didn't think about it too much. I didn't feel like I was sick at that point. So there wasn't anything to treat almost. I was also – I was quite worried about having a liver biopsy as well, obviously being a haemophiliac, and also I kind of heard that the combination of ribavirin and interferon, the side effects can be quite extreme. So ... I just didn't really consider it.<sup>669</sup>

**6.341** As he grew older Alex began to consider what the virus might mean for him and so he started on 'a personal quest for information'. He was scared of what he was going to find out. He obtained booklets from the hospital.<sup>670</sup> He gained the impression that those infected with Hepatitis C generally lived for 15 to 20 years. He saw other haemophilia patients dying. As a result of this, he did not think that he would live long past his teen years. He stated:

[I]t is hardly surprising that I lacked the motivation and ambition to work hard and gain qualifications for a 'future' that no-one could assure me I would have

---

<sup>669</sup> Day 81, page 78

<sup>670</sup> Ibid, page 74

.... So I just didn't try. I gave up before I had even started and at the age of 16 dropped out of education with few standard grades and no ambition.<sup>671</sup>

### *The period after Alex left school*

**6.342** Alex started to attend Dr Morris' Liver Clinic annually. An abdominal ultrasound in August 2001 was normal.<sup>672</sup> In 2002, at the age of 16, Alex began a course at his local college. He spent less than a year on this course and then moved to Glasgow to study on another course. He completed the first year of this course. He found it difficult being away from home and thinks that he was perhaps too young to have moved away from home. At his annual reviews at Dr Morris' clinic his position with regard to treatment remained the same:

I was quite happy just to go in and ... get them done and leave really. Also, I didn't find I had any problems relating to my Hepatitis C at that point. I wasn't really interested in treatment or exploring anything any further. I did look into treatment myself a little bit but I didn't want to pursue it.<sup>673</sup>

Throughout this period Alex suffered from fatigue. He would suddenly become 'really, really tired' but he did not associate it with Hepatitis C.<sup>674</sup>

**6.343** Over time Alex became more concerned about the progression of the virus. When asked what caused this he stated:

I think it was a combination of a lot of things. I was finding it quite hard living in Glasgow and getting around the city, just even my joints and things were starting to seize up. My knee was getting especially bad and I think I – over a short period of time I just started to care a bit more that I had Hepatitis C and I started to almost think about it and research it. And I guess over a period of time it just hit me that it is actually really serious.<sup>675</sup>

**6.344** During his research Alex found something on the internet or elsewhere that said that patients with Hepatitis C can expect to live for 20 years. As he was nearing his 20th birthday he thought that his 'time was getting kind of close'.<sup>676</sup> Also at this time Alex's mother became unwell. Alex voiced his concerns to an Associate Specialist in the haemophilia and thrombosis centre at Glasgow Royal Infirmary. In April 2007, this doctor wrote to Dr Morris and asked him to see Alex ahead of his next appointed clinic time, with a view to discussion of possible biopsy and treatment. Unfortunately, Dr Morris was about to take a sabbatical and so was unable to see Alex until the appointed clinic in October 2007. When Alex attended this appointment he was seen by a junior doctor. During this appointment Alex asked this doctor some questions. A number of times the doctor left the room to discuss Alex's questions with Dr Morris, who was in the room next door. Having reconsidered the possibility of treatment, Alex would have liked to have had the opportunity to speak to Dr Morris personally on this occasion. At this appointment it was decided that Alex should undergo an ultrasound-guided liver biopsy which required him to be admitted beforehand to correct his clotting, and then afterwards for observation.<sup>677</sup>

---

<sup>671</sup> Alex's additional Statement

<sup>672</sup> Day 81, page 77; Excerpts from the medical records recovered in respect of Alex

<sup>673</sup> Day 81, page 80

<sup>674</sup> Ibid, page 81

<sup>675</sup> Ibid, page 82

<sup>676</sup> Ibid

<sup>677</sup> Excerpts from the medical records recovered in respect of Alex

**6.345** Later in 2007 Alex attended the Glasgow Royal Infirmary (GRI) to undergo the liver biopsy. Before attending for this procedure Alex researched it on the internet. He found a lot of information but was unsure which details were correct, 'But I had made a mental decision that maybe now is the time to do something about it and if I have to get a biopsy to get the treatment, maybe it's worth it'.<sup>678</sup> Having been admitted to the hospital for the procedure, and had a cannula inserted into his hand, Alex changed his mind about having a liver biopsy. One reason for this was that the liver specialist nurse came to speak to Alex to make sure that he wanted to go ahead with it. She asked Alex if he knew what genotype of the virus he had, and Alex told her that he did not know. She told Alex that the genotype of the virus he had would have 'a massive impact on the treatment and the success rate'.<sup>679</sup> She went away to find out his genotype. On her return she told Alex that he had Genotype 1 and so he had a much lower chance of clearing the virus than if he had one of the other genotypes. Another factor which contributed to Alex's decision to postpone the procedure was that his Haemophilia Consultant came from upstairs to check on Alex. He told him that it was a fairly serious procedure for a person with haemophilia to undergo, and seemed to want to make sure that Alex understood fully the implications of having a liver biopsy. Alex believes that, until his discussion with the Haemophilia Consultant, he had not fully appreciated the risks of a liver biopsy. The fact that two people checked on him and asked him if he wished to continue with the procedure scared Alex: 'At that point [he] said, "Maybe I need to think about this. Maybe I need to think whether I'm doing the right thing"'.<sup>680</sup> He left the hospital without undergoing the procedure.

**6.346** In February 2008 Alex moved from Glasgow to another city in the UK. By this time Alex had managed to complete only two years of his college course in Glasgow. Alex's attendance on the course was poor. He believes that this was due to his haemophilia and the fact that, during this period, he became preoccupied with the fact he had Hepatitis C. He also found it difficult to concentrate.<sup>681</sup> He found it hard to get close to people and was quite withdrawn.<sup>682</sup> Alex decided to move to this new city as his girlfriend at the time lived there, and he knew that there was a good hospital there. On moving Alex started attending a joint hepatology and haemophilia clinic at the local hospital every six months. He believes he receives good care there. This care includes Fibroscans. These scans use transient elastometry to measure the amount of liver stiffness, from which the level of fibrosis can be assessed. His Fibroscan result in 2010 was 6.8kPa.<sup>683</sup>

**6.347** His blood test results from April 2010 revealed an albumin 46g/L, alkaline phosphatase 77iu/L, AST 62 iu/L, ALT 107 iu/L and bilirubin 10 mmol/L. His viral load was 1.7 million, suggesting that that there was not major liver fibrosis, that the liver was functioning well, but that the virus was still actively reproducing.

### *The present position*

**6.348** Alex has been advised by the doctors in this new hospital that he should consider treatment for the Hepatitis C virus while he is healthy enough to withstand the side-effects. Understandably this change in advice has caused Alex to become confused about what

<sup>678</sup> Day 81, page 87

<sup>679</sup> Ibid, page 86

<sup>680</sup> Ibid, page 86

<sup>681</sup> Alex's Witness Statement

<sup>682</sup> Day 81, page 90

<sup>683</sup> Excerpts from the medical records recovered in respect of Alex; a score of over 7.2kPa indicates higher likelihood of significant fibrosis.

would be the best course of action for him. Some time in 2011, Alex was offered treatment with Interferon and Ribavirin and was on the verge of accepting it. His doctor then advised him that he might be better waiting for the new treatment of protease inhibitors.<sup>684</sup>

**6.349** Alex believes that he has suffered from symptoms of Hepatitis C throughout his life although 'sometimes [he] did not realise the full extent of them'.<sup>685</sup> He has often been depressed, angry, tired and lethargic. Alex has never received treatment for depression although he did once mention how he felt to his GP in Glasgow.<sup>686</sup> Alex's father stated that after Alex started his treatment with Interferon he:

[W]as just going away all on his own, wouldn't come out. He would spend days and he would hardly eat and we just thought, well, it's just the effect of the interferon that's causing it, but obviously it wasn't. It was just an ongoing thing right up until he moved away from home ....<sup>687</sup>

He told the Inquiry that he found it hard to speak to his parents or anyone else because 'all my experiences of going to the hospital were very negative, so everything surrounding having haemophilia and Hepatitis C was all really negative'.<sup>688</sup> He tried on occasion to speak to his mother about it but 'it wasn't a very nice thing to do. I always found it ... really hard'.<sup>689</sup> Alex's family, especially his mother, cared for him extensively as he grew up and Alex now relies heavily on his girlfriend.

**6.350** Alex has been given limited advice about the prognosis for his condition. He has tried to research it himself but has never fully understood it.<sup>690</sup> He believes that:

[I]t is so complicated to even consider having children that I just don't bother. The risk of passing on an infection and then the thought of not being around to see my children grow up really prevents me from planning any kind of family life.<sup>691</sup>

He has discussed this with his doctor and has been told that there is a risk of passing on the Hepatitis C virus. He understands that there are alternatives, such as IVF, which would lower the risk of infecting his partner but, although Alex would love to have children when he is older, he is not considering it at present.

### *Specific impacts of Alex's infection with Hepatitis C*

**6.351** Alex's father stated that the family is very close and that it has been 'heart breaking' that one of the five of them has had Hepatitis C. It had a 'huge' effect on Alex's late mother, and Alex appreciates that his having haemophilia and then Hepatitis C was 'a lot to go through'.<sup>692</sup> He feels responsible for having put his parents through this. It was apparent from Alex's evidence that his diagnosis with haemophilia and then Hepatitis C has put a strain on both his parents, in particular his mother as his main carer, and his family life. Although they are close, Alex described himself as 'quite closed' and stated that '[A]s a family we generally don't talk about it. It's always there, obviously, but it's hard to talk about'.<sup>693</sup>

<sup>688</sup> Ibid

<sup>689</sup> Ibid

<sup>690</sup> Ibid, page 97

<sup>691</sup> Ibid, page 98

<sup>692</sup> Ibid, pages 98–99

<sup>693</sup> Ibid, pages 99–100

**6.352** The diagnosis with Hepatitis C has affected his social life. He finds it difficult to get close to people because then he feels that he needs to tell them about his condition:

It's this whole big thing that you have to explain. It's not like you can tell every person you meet and have a quick explanation of 'Oh, that's a shame. It's terrible that could have happened'. You have this whole other big baggage of information that you have to carry and explain. I almost feel like I have to defend it if I do tell anybody, which is why I generally choose not to.<sup>694</sup>

**6.353** As a result of this he does not have a large circle of friends and does not become involved in community life. Alex worries that he may sustain an injury causing him to bleed, and then he will have to tell people he has Hepatitis C.<sup>695</sup>

**6.354** In 2009 Alex underwent an arthroscopy to repair damage to his right knee, one of his target joints. This had a good effect. Alex is generally confined to non-physical activities which is due both to his haemophilia and Hepatitis C. He is unable to play impact sports of any kind. He finds it difficult to do activities which keep him fit as he finds that he tires easily.<sup>696</sup>

**6.355** After Alex left Glasgow he started studying again. Now he has part-time, unpaid work, the nature of which he wishes to remain confidential. This work is relaxed in that he can take breaks when he wishes and he can work from home. The people he works with are accommodating with regard to his haemophilia. Alex told his employers about this when he started working there. He hoped that his work there would become full-time within the next month or so. In the past Alex has found it difficult to sustain any level of work. His lack of qualifications on leaving school limited the career options open to him. During the time he was at college Alex tried to work in bars and coffee shops but he found such jobs difficult to maintain due what he described as 'the immense bouts of fatigue' from which he suffered and the unpredictability of them.<sup>697</sup> He stated that, on occasion, he has had to turn down or leave other work due to his symptoms of Hepatitis C.<sup>698</sup> As a result of this Alex felt that he was unreliable in the work place and not the best kind of employee. 'I feel like a bit of a failure on the work front and it is always difficult when I compare myself with friends my age who seem to be progressing with their lives'.<sup>699</sup> Due to his uncertainty about his future, motivation has been hard for him.

**6.356** For number of years Alex has had to rely on benefits. Nobody else in his family has ever claimed benefits and the fact that he does so is something he feels guilty about: 'I have never enjoyed it or been proud of it'.<sup>700</sup> Over the years Alex has accumulated debts, including an overdraft and credit card bills, amounting to about £18,000. He stated that he was reckless with money as he was immature and did not think he was going to live long enough to have to pay these debts off. At one time he was called by debt collectors almost every day and this caused him a lot of anxiety. He has now consolidated his debts and feels that he is more in control of his finances. He has started to make payments to reduce the debt and hopes eventually to repay it. In 2004 Alex received £20,000 from the Skipton Fund, and he paid off some debts, gave some money to his family and paid rent on his accommodation in Glasgow.

<sup>695</sup> Ibid, page 102

<sup>696</sup> Ibid

<sup>697</sup> Ibid, page 103

<sup>698</sup> Alex's additional Statement

<sup>699</sup> Day 81, page 104

<sup>700</sup> Ibid, page 105

**6.357** Alex believes that his diagnosis with Hepatitis C precludes him from obtaining a mortgage and so he is unable to consider buying a house. He has never applied for a mortgage but has researched obtaining one. The expense of travel insurance, and Alex's financial situation makes it difficult for him to travel abroad. On one occasion Alex travelled to the USA with his parents. His parents' travel insurance cost £32, but Alex's cost £109 due to his haemophilia and Hepatitis C. He wishes he was able to travel more.<sup>701</sup>

**6.358** When Alex was a child, the costs of his travel to the Haemophilia Unit at Yorkhill, and that of the parent who accompanied him, were paid for by the Health Board. They usually stayed with Alex's aunt. They were given an allowance of £28 a night for accommodation. This was insufficient to cover the cost of this, particularly if they were unable to stay with a relative. Alex's parents paid the rest of their costs of these trips from their savings. Alex's father stated: '[I]t was quite a big chunk of any savings that we had'.<sup>702</sup> A disadvantage for Alex of staying with his aunt was that after each hospital visit he had to answer her questions, and explain what had happened, at the appointment. He found this difficult and gave the impression he would have preferred not to have had to speak about his appointments.

**6.359** Alex feels the cold and has bad circulation in his toes and fingers. This may be a symptom of Hepatitis C. As a result of this he has incurred increased heating costs. Occasionally when Alex's symptoms of Hepatitis C are severe, he employs a cleaner and a handyman. He bears the cost of this. He stated that his girlfriend often has to look after him now.<sup>703</sup>

**6.360** In a written statement to the Inquiry about the financial effects of his infection with Hepatitis C, Alex wrote:

I feel like I have lost my future. I find it hard to assess exactly how much financial hardship I have faced as a result of my illness because it is difficult to measure potential. I can compare myself to my siblings and peers, all of whom have successful jobs, own their own houses and have a good quality of life. At the age of ... I have none of these things and I can only put this down to being different and the difference is my illness. I know I am intelligent, I know there are a lot of things I would have loved to have done, but my illness, and in particular the lack of support and information I was given growing up, has prevented me ever achieving anything. I can't hold down a job as I am just not reliable, I would not employ me and I [am] embarrassed that as a ... year old man I have never really achieved anything. I just want a fresh start but I feel trapped in my situation – I rely on benefits and don't have the finances to re-enter education and start my life again. I feel I will always be reliant on others for my life and the burden of that makes me just want to give up.<sup>704</sup>

## Christine

**6.361** Christine's son contracted HIV from contaminated blood products and she gave evidence during the Oral Hearing in support of Chapter 5, *The Effect of Infection with HIV, Including the Effects of Treatment, on Patients and their Families*. Christine herself contracted

---

<sup>701</sup> Ibid, pages 107–108

<sup>702</sup> Ibid, page 109

<sup>703</sup> Alex's additional Statement

<sup>704</sup> Alex's additional Statement

the Hepatitis C virus from blood products, and her account of some of the effects of this on her, and her family, is narrated below. It is likely that these are understated as Christine's evidence to the Inquiry mainly focused on her son's infection with HIV. In order to gain a fuller appreciation of the impacts of Christine's infection with Hepatitis C, what is written below should be considered together with the evidence narrated at paragraphs 5.5 to 5.62.

### *How Christine acquired Hepatitis C*

**6.362** At the date of the hearing Christine was in her mid-50s.<sup>705</sup> She had a family history of haemophilia, with her two brothers, a cousin and an uncle being diagnosed with it.<sup>706</sup> In 1975 following the birth of her son, who was referred to in evidence as 'John', and his diagnosis with Haemophilia A, Christine was investigated and found to be a carrier of Haemophilia A.<sup>707</sup>

**6.363** As a result of being a carrier of Haemophilia A, Christine decided to undergo sterilisation. She found this a very difficult decision to make. The surgery was carried out in December 1981 at a hospital elsewhere in the west of Scotland. Prior to the surgery, Christine's Factor VIII levels were checked by her son's Consultant Haematologist at Yorkhill Hospital and were found to be 26%. She had never had any bleeding problems.<sup>708</sup> But when she regained consciousness after the operation, Factor VIII was being administered to her. Christine asked the medical staff to stop this treatment. She felt that they were 'making a mountain out of a molehill'.<sup>709</sup> Christine made her unhappiness clear and was told that she had signed a waiver consenting to the administration of any treatment thought necessary.<sup>710</sup> She later learned that the administration of Factor VIII had been at the suggestion of the Haemophilia Unit at Yorkhill, with the Factor VIII being sent over in a taxi from Yorkhill at the time of her operation.<sup>711</sup> It was 2800 units of Armour Factor VIII, batch number VC2103, which proved to have been infected with Hepatitis C.<sup>712</sup> This was the only time Christine received human Factor VIII concentrate.<sup>713</sup>

**6.364** Immediately following the sterilisation procedure, Christine had acute jaundice and felt extremely nauseous for a week. She was treated for this by her GP. Having not been warned specifically of any risks associated with Factor VIII, she did not think there was any link between it and her symptoms. Christine was told by one of the nurses that, as a result of her having suffered jaundice, the batch of Factor VIII which she had received was withdrawn from use as a safety precaution.<sup>714</sup> The cause of Christine's episode of jaundice was investigated by her GP, and markers for Hepatitis A and B were negative. There was no further follow-up of liver function tests or other viral markers.<sup>715</sup>

**6.365** In December 1981 Christine was referred to the Haemophilia Unit at the Glasgow Royal Infirmary to be registered as a haemophilia carrier. She has attended the Haemophilia Unit annually for routine blood tests. Since 1981 she has had synthetic desmopressin (DDAVP) cover for all major and minor surgery, including for a hysterectomy in November 1988.<sup>716</sup>

<sup>715</sup> Ibid, page 30; Excerpts from the medical records recovered in respect of Christine

<sup>716</sup> Day 28, pages 31–32; Christine's Witness Statement

### *Christine's symptoms of Hepatitis C*

**6.366** After 1981 Christine suffered from skin itching, arthritis and painful feet. She had episodes of insomnia and extreme tiredness but generally kept good health. She attributed her tiredness to a combination of factors, namely caring for her elderly mother and working hard, as she did.<sup>717</sup> Later she had also to deal with the challenges presented when her son was diagnosed with HIV.

### *Christine's diagnosis with Hepatitis C*

**6.367** Christine did not find out that she was infected with Hepatitis C until 1991. A couple of weeks after giving blood at a mobile blood transfusion centre she was asked to attend a meeting at the Glasgow offices of the SNBTS. She did not know what the meeting was about. At this meeting she was told by an unidentified individual that, having tested her blood donation, it had been discovered that she was positive for Hepatitis C. Christine could not believe this and was in shock. After she was questioned about whether she had taken any drugs or medication, it was suggested to her that she could have acquired the virus from the Factor VIII she was given in 1981. It was never confirmed to her that this was the source of her infection. She does not recall being given any information at this meeting about the virus except that she was told that she should not donate blood again and not to consider organ donation. She stated that if she was given any more information than that, she was in too much of a shock to absorb it. She was advised to attend her GP.<sup>718</sup>

**6.368** Christine believes that she was not properly counselled when she was told she had Hepatitis C. She was not told to practise safe sex and she was not warned that she could be at risk of HIV from the Factor VIII she received in 1981. She believes that had she not donated blood, she would not have discovered that she had the virus.<sup>719</sup>

### *Christine's treatment for Hepatitis C*

**6.369** As suggested to her, Christine attended her GP and he referred her to the Hepatology clinic of Dr Mills, Consultant Hepatologist at the Gartnavel General Hospital, Glasgow. Christine attended this clinic in 1991. There she was advised by Dr Mills to start treatment with a 48-week course of Interferon and she did so. During the treatment she suffered side-effects and described the treatment as 'horrible'.<sup>720</sup> Immediately after taking the treatment she felt very ill. She suffered from flu-like symptoms, her joints were sore and she became very tired. She was working full-time and in order to cope with the treatment, she used to inject herself with the Interferon in the early evening, and then immediately go to bed. Unfortunately, tests 12 weeks after the treatment started showed that it had been ineffective and so, in accordance with practice at the time, the treatment was stopped. Christine was very disappointed.<sup>721</sup>

**6.370** Thereafter, Christine continued to attend the liver clinic for monitoring once a year. Liver biopsy was considered to be too risky for her. She has had annual liver function tests and Hepatitis C RNA tests. She has a two-yearly liver scan performed. In January 2010 Christine underwent a new sonar pulse scan which produced a 3D picture of her liver. She was told that her liver was no more affected than to be expected for a person of her

age. Later in 2010, Christine started a 48-week course of treatment with Interferon and Pegylated Interferon. The side-effects of this were similar to those she experienced during her previous course of treatment. She felt very tired and she felt sick.<sup>722</sup> She stated, 'I must have been a nightmare to live with because I felt as if I was living a nightmare'.<sup>723</sup> Christine completed this course of treatment shortly before she gave evidence to the Inquiry in June 2011. At the end of the treatment she was negative for the virus, but was warned that the virus could still return.

**6.371** Christine received a payment of £20,000 from the Skipton Fund.<sup>724</sup>

### **Patients' experience – Conclusion**

**6.372** Chapters 4, 5 and 6 have dealt with the experiences of the patients and relatives. In conclusion the Inquiry is very grateful to the many witnesses who came forward and provided evidence about the effects of their own or their relative's infection with HIV and/or Hepatitis C.<sup>725</sup> At the heart of this Inquiry lies the fate of people who, simply by accepting treatment for a medical condition, contracted either HIV or Hepatitis C, or both these viruses. In many cases the infections were acquired because of treatment for a blood coagulation disorder, such as Haemophilia A or Haemophilia B. Those with these disorders had already suffered to varying degrees as a result of their underlying conditions. Others became infected as a result of a single blood transfusion, sometimes being unaware until later that they had even been transfused. Whatever the route of transmission, suffering resulted – whether to the patients themselves or to their relatives. The pain they felt cannot be quantified. Many people have had their lives shaped and overshadowed by a loved one's illness. Many people have had to watch their loved ones, including children, suffer. In some cases, they have had to watch them decline and die.

**6.373** The stigma which some feel persists, even today, in relation to both viruses, made it particularly difficult for some witnesses to contact the Inquiry. These witnesses had to overcome fear of disclosing their own identity in order to do so. The Inquiry put in place a number of measures to maintain confidentiality. These are described in Appendix 2 to this Report.

**6.374** Hearing the personal stories was a fundamental part of the Inquiry and it would not have been possible without the witnesses being so willing and open. For many, giving statements was their first opportunity to share the experiences of what had happened to them in the course of NHS treatment. Some told of adverse consequences which they had not disclosed to even their closest family members. It is hoped that by telling their stories to the Inquiry and making them available for publication these witnesses felt that they had been heard.

**6.375** As was stated at the start of this section of the Report, the evidence of the patient and relative witnesses makes its own impact and it would be inappropriate to single out particular aspects for comment. What can be said is that the Inquiry heard many tales of truly extraordinary bravery in the face of adversity. There were also tales of resignation and tales of rage. For all patients and relatives the consequences of infection were at least distressing, for many they were devastating and, for some, tragic.

---

<sup>722</sup> Ibid, pages 36–37; Christine's Witness Statement

<sup>723</sup> Day 28, page 37

<sup>724</sup> Ibid, page 108; Christine's Witness Statement

<sup>725</sup> The process involved in providing a witness statement to the Inquiry is described in Appendix 2

**6.376** The Inquiry is particularly indebted to those witnesses who agreed to give oral evidence to the Inquiry. In doing so, these witnesses opened their lives up to intense scrutiny by others. As will be apparent from the narration of their evidence, each of these witnesses was both candid and brave. In recounting their stories they required to revisit very difficult, painful and sad times in their past as well as recounting ongoing effects which, understandably, they might be trying to forget. Some of the witnesses became visibly distressed when giving their evidence while others showed quiet stoicism. The impact of their evidence was felt by all those present and everyone was moved by it. It is hoped that the narration of the evidence of each of these witnesses in such detail is able to convey, as closely as possible, the power of it. This evidence illustrated just how far into a person's life the impacts of infection could reach. Of course it must be remembered that for each of these stories there are others, every one unique and compelling in its detail.

**6.377** Finally, it is a matter of sorrow to the Inquiry team that some of the witnesses who provided statements and Gordon, who gave oral evidence to the Inquiry, died before this report was published. Gordon impressed all those who heard his evidence as a dignified and intelligent man. Like others, he took a great interest in the work of the Inquiry and he did all he could to assist with its task.

## CHAPTER 7

### AN INVESTIGATION INTO THE DEATHS OF THE REVEREND DAVID BLACK, MRS EILEEN O'HARA, MR ALEXANDER BLACK LAING AND MR VICTOR TAMBURRINI

#### Introduction

**7.1** The matters which the Inquiry was asked to investigate and report upon were set out in the Terms of Reference issued up by the Cabinet Secretary for Health and Wellbeing, following consultation. Term of Reference 6 required the investigation of the deaths of certain named individuals with particular reference to the circumstances in which they became infected with Hepatitis C, HIV or both. In the event, none had acquired infection with HIV.

Term of Reference 6.

To investigate the deaths of Reverend David Black, Mrs Eileen O'Hara, Alexander Black Laing and Victor Tamburrini, with particular reference to the circumstances in which they became infected with the Hepatitis C virus, HIV or both.

**7.2** Originally, the Inquiry was required to investigate the deaths of Reverend Black and Mrs O' Hara only. Those particular deaths were selected as the personal representatives of the two deceased had raised proceedings in the Court of Session to challenge decisions made by the Lord Advocate and the Scottish Ministers, respectively, not to investigate the circumstances of those deaths. In February 2008 the Court of Session quashed the Lord Advocate's decision. The Scottish Ministers' decision was not then quashed having regard, amongst other things, to the fact that on 16 June 2007 the Scottish Government had re-affirmed its commitment to hold 'a general Public Inquiry' to 'find out why people were infected with Hepatitis C through NHS treatment'. Upholding that commitment, on 23 April 2008 the Scottish Ministers set up this Inquiry under the Inquiries Act 2005. On 13 November 2009, the Scottish Ministers added three further deaths for investigation: Mr Laing, Mr Tamburrini and Mr Neil Mullen. On 22 February 2011, however, at the request of his family, Mr Mullen's name was removed from the list of deaths to be investigated. As noted above, none of the individuals whose deaths the inquiry was asked to investigate was infected with HIV.

**7.3** As the personal representatives of the deceased were expected to have a key role during the Inquiry, they applied for and were designated as Core Participants. In addition, they were awarded funding for their legal representation, which was provided through Thompsons, Solicitors. The four personal representative Core Participants were:

- Mrs Jean Black as the personal representative of the Reverend Black.
- Mrs Roseleen Kennedy as the personal representative of Mrs O'Hara.
- Mrs Annie Laing as the personal representative of Mr Laing.
- Mrs Jean Tamburrini as the personal representative of Mr Tamburrini.

**7.4** An important early step in the investigation process was the obtaining of the medical records of the deceased. Principals were obtained where they existed. Records were recovered from the relevant Health Boards and the Crown Office and Procurator Fiscal Service. Documents were also recovered from the Scottish National Blood Transfusion Service (SNBTS).

**7.5** Suitable medical experts were identified and instructed to provide independent, expert reports in order to help focus the issues for investigation into each of the deaths. The expert reports were circulated for observation and comment to the legal representatives of all the Core Participants which, in addition to the personal representatives, included Haemophilia Scotland, the Scottish Ministers, the SNBTS,<sup>1</sup> the 14 Scottish Area Health Boards and 15 individuals as representative of classes of patient interests.

**7.6** Written statements were taken from the personal representatives of the deceased and other individuals.

**7.7** The public hearings began with the taking of detailed evidence relating to each of the deaths. This approach was adopted in order to ensure that any issues which arose in the course of those investigations and which had significance beyond the individual death under consideration could be noted and explored subsequently in the course of the topic-based investigations. Accordingly, information obtained as a result of the intense scrutiny to which each death was subjected assisted in understanding important systemic issues which were of relevance in the later consideration of many of the additional terms of reference. Evidence on the deaths was heard over four days, from 8–11 March 2011 and 12 witnesses appeared in order to assist the Inquiry in this matter.

**7.8** Immediately following the conclusion of this evidence, a public session was held at which Senior Counsel for the Inquiry and Counsel representing the Core Participants sought to identify systemic issues arising from the evidence. In the event, no issues additional to those already scheduled to be covered in hearings arose from evidence in relation to the specific deaths.

**7.9** Before the conclusion of the Oral Hearings phase of the Inquiry, all Core Participants' legal representatives were invited to make written submissions on what they considered to be the questions and issues arising from the evidence. They were also permitted to comment upon the written submissions of other Core Participants.

**7.10** The personal representatives of the deceased, Haemophilia Scotland and the patient interest Core Participants, who were all legally represented by Thompsons, Solicitors, jointly made written submissions in relation to the deaths. The SNBTS and the Health Boards, jointly represented by the Central Legal Office of the Common Services Agency, provided comments in relation to the submissions on the Reverend Black and Mr Laing.

**7.11** Having considered all the evidence before the Inquiry, this chapter sets out the Inquiry's findings in relation to each of the deaths.

## **Reverend David Black**

**7.12** Mr Black was born on 1 May 1937. He died on 31 October 2003 at Strathcarron Hospice, Stirlingshire. The cause of death was registered as hepatocellular cancer in a transplanted liver, Hepatitis C, transfusion of blood products and haemophilia.<sup>2</sup>

---

<sup>1</sup> The SNBTS is one of the health support services provided by the Common Services Agency (CSA) for the Scottish Health Service. The CSA is the designated Core Participant on behalf of the SNBTS.

<sup>2</sup> Death Certificate [BLA.001.2118]

## Mr Black's early medical history in relation to haemophilia

**7.13** There was a history of haemophilia in Mr Black's family.<sup>3</sup> He was diagnosed as having the disease in the early 1940s when he was five.<sup>4</sup> A possible alternative diagnosis of von Willebrand's disease<sup>5</sup> was considered in the early 1970s.<sup>6</sup> However, his von Willebrand Factor antigen was 65% of normal, the relevant bleeding time test was normal and the correct diagnosis was almost certainly Haemophilia A.<sup>7</sup> When his condition was investigated, it was found that he had a resting Factor VIII level of between three and seven international units per decilitre (3–7%).<sup>8</sup> Along with his history of treatment, that was consistent with mild to moderate Haemophilia A.<sup>9</sup> For the purposes of this Report, that diagnosis is accepted.

**7.14** Mr Black's early medical history was typical of a child with relatively mild haemophilia. He did not have haemarthrosis (bleeding into his joints) or spontaneous bleeding. He required occasional treatment with blood, blood components and blood products in response to specific events, however. Mr Black was probably first treated aged five when he had a haemorrhage; thereafter, on his own account, he was given 'transfusions', mainly for procedures such as tooth extractions from time-to-time.<sup>10</sup> His early records were incomplete: it was recorded that he had been given blood or plasma once at Edinburgh Sick Children's Hospital and twice at Glasgow Western Infirmary.<sup>11</sup> In October 1965, it was recorded that he had received plasma once at the Glasgow Royal Infirmary (GRI), in 1957, when he had a sudden episode of haematuria (blood in the urine).<sup>12</sup> He was treated at various times at Professor Alexander Douglas' clinic and by Dr Paul Davis, Dr Colin Prentice and Professor Gordon Lowe (who would become Co-Director of the Glasgow Hemophilia Centre in 1988).

**7.15** More detailed records were available from the 1960s and Mrs Black was able to supplement these from her own recollection. Mr and Mrs Black met in 1961.<sup>13</sup> Mrs Black had been a nurse and was more familiar than some with the diseases and terminology relevant to the Inquiry.<sup>14</sup> The account of Mr Black's medical history reflects her evidence in addition to evidence drawn from Mr Black's medical records. Mrs Black was rather frail at the date of the Inquiry's Oral Hearings. So far as her positive recollections are concerned, her written witness statement is accepted as generally true and reliable. Not surprisingly, there are omissions from her account and some of these at least were made good by the medical records.

**7.16** Mr Black was admitted to the GRI on 20 October 1965, then aged 28, for a tooth extraction. He was given four flasks of antihæmophilic globulin (AHG), an early form of NHS Factor VIII concentrate prepared in Edinburgh.<sup>15</sup> AHG was a crude plasma product

<sup>13</sup> Witness statement of Mrs Black [PEN.001.0011]

<sup>14</sup> Statement by Counsel to the Inquiry – Day 2, page 69

<sup>15</sup> GRI report to GP dated 11 November 1965 [BLA.001.2204]; GRI Haematology form dated 22 October 1965 [BLA.001.2200]. Bottles identified as 3019C; 2727C; AF3097; 3013B without further description. The product was prepared by Cohn fractionation. The process is described in Chapter 20, *Haemophilia Therapy – The Period up to the Early 1980s*.

and Mr Black was given phenergan and cortisone, probably to reduce or eliminate the risk of an allergic reaction to the treatment. In the event, the extraction was without difficulty and bleeding was not troublesome.<sup>16</sup>

**7.17** The next recorded hospital visit was in May 1969 when he again required dental treatment.<sup>17</sup> On this occasion he was probably treated with cryoprecipitate, a frozen plasma product derived from a single donor's blood. AHG was by this point in short supply; by that date, treatment with cryoprecipitate was in general use throughout the UK.<sup>18</sup>

**7.18** Mr Black also received treatment abroad. Though specific instances are recorded, there is inevitably a lack of certainty about his history of treatment in other countries. He was a Baptist minister and worked both in the USA and in developing countries. At one point he worked for Oxfam. After their marriage, he, Mrs Black and their family travelled widely. Inevitably, there is a risk that his Scottish medical records do not reflect all of the treatment he received and some of his known history depends solely on Mrs Black's recollection.<sup>19</sup>

**7.19** Mrs Black said that her husband received blood products in San Jose, California, in 1970 when treated for a kidney stone.<sup>20</sup> He was working in South Korea at the time and was treated en route to or from there.<sup>21</sup> At this time, US pharmaceutical companies were in the vanguard in developing large-pool concentrates (concentrates, that is, prepared from a large number of donations from a large number of donors). Clinicians there were ahead of UK doctors in the use of concentrates: Dr Brian Colvin<sup>22</sup> said that he and his colleagues at the London Hospital were just beginning to use them in 1970. He thought that it was entirely possible that treatment received by Mr Black in the USA in 1970 would have involved an American large-pool concentrate.<sup>23</sup> A positive finding to that effect cannot be made, however, as cryoprecipitate continued to be the therapeutic material of choice for some clinicians at this time. Mr Black was treated by Dr Judith Pool in Stanford Medical Centre.<sup>24</sup> Dr Pool, noted by Dr Colvin as the 'founding mother' of modern haemophilia care, described the preparation of cryoprecipitate in 1964 and 1965<sup>25</sup> and reported use of that product in 1966.<sup>26</sup> It is not unlikely that she would have continued to use cryoprecipitate, the product she had devised and developed, even though early forms of large-pool concentrates were becoming available. It is not possible to resolve the issue of which product she may have used to treat Mr Black in 1970.

**7.20** For a period after 1970, Mr Black had no treatment in the UK. He was referred to the GRI following his treatment in the USA<sup>27</sup> and had tests in April and May 1971.<sup>28</sup> In April, he reported no haemostatic problems and the examination disclosed no other problems at that time apart from some slight tenderness over the left renal angle (the area

<sup>27</sup> GP request to GRI for out-patient consultation dated 22 March 1971 [BLA.001.2153]

<sup>28</sup> Letter from GRI to Dr Pool dated 07 April 1971 [BLA.001.2152]; letter from GRI to GP dated 9 April 1971 [BLA.001.2151]; and see Mr Black's hospital notes [BLA.001.2218]

of the lower back around the site of the kidney).<sup>29</sup> In May, he was seen by Dr J F Davidson, who reported that Mr Black was still complaining of vague ill-health, with an ache in his right lumbar region, and that they could find no cause for his backache.<sup>30</sup> On 7 February 1973, the Regional Haemophilia Centre wrote to him asking him to attend in order to bring his records up to date, as he had not been reviewed at the Centre for four years.<sup>31</sup> In February 1974 he had chest pains and was referred to the GRI.<sup>32</sup> In May 1974, he reported that he had been keeping fairly well and had not had bleeding problems, although he again expected to need dental treatment.<sup>33</sup> Mr Black appears to have changed GPs about mid-January 1975. A letter dated 17 January 1975 was sent to his new GP informing him of the Haemophilia Centre's interest. The letter commented that Mr Black did not appear to have any problems except when faced with a haemostatic challenge (such as trauma, surgery and dental extractions); when that occurred, he would require active Factor VIII replacement therapy.<sup>34</sup> That was consistent with his recorded history up to that point.

**7.21** On 26 and 27 June 1975, Mr Black attended the GRI with pain in his left knee. On clinical examination this was thought to relate to a haematoma (subcutaneous clotted or partially clotted blood) rather than a haemarthrosis. He had factor replacement therapy at that stage, probably with large-pool concentrate.<sup>35</sup> In May 1978 he required SNBTS Factor VIII concentrate and cryoprecipitate to support a tooth extraction.<sup>36</sup> In February 1979, Mr Black again had cryoprecipitate prior to a dental extraction and, on this occasion, also to deal with post-extraction bleeding.<sup>37</sup>

## Evidence of Hepatitis C infection

**7.22** Mr Black was reviewed in the autumn of 1976<sup>38</sup> and in the spring of 1978.<sup>39</sup> He did not report any bleeding problems but on the second visit complained of chest and abdominal pains. Tests were negative for abnormalities of the oesophagus, stomach and duodenum (the first section of the small intestine) and there was no evidence of a peptic ulcer.<sup>40</sup> In September 1978, his condition was unchanged and he reported no new problems.<sup>41</sup> There were no recorded signs of hepatitis infection at that time, although, in retrospect, his blood test results can be associated with Hepatitis C infection.

**7.23** On 14 December 1979, elevated liver function test results were recorded for the first time when his transaminase GOT<sup>42</sup> was 97.<sup>43</sup> The majority of his liver function test results after this date were abnormal.<sup>44</sup> As the natural history of the disease is now understood, this was typical of Hepatitis C infection, then covered by the umbrella term 'non-A non-B Hepatitis' (NANB Hepatitis). There were few diagnoses of NANB Hepatitis in Scotland

<sup>42</sup> 'Transaminase GOT' is Glutamic-oxaloacetic transaminase, a blood enzyme. GPT (Glutamic-pyruvate transaminase), another blood enzyme, was also elevated. According to Dr Colvin (Day 2, page 97) normal levels for both are about 40. Other 'liver function tests' more frequently referred to in the records are Alanine Aminotransferase (ALT) and Alkaline-phosphatase tests. They have broadly the same significance in the diagnosis of hepatitis.

<sup>43</sup> GRI Blood Investigation Sheet [BLA.001.2232]

<sup>44</sup> Dr Colvin's report [BLA.001.2281] at 2284

before the late 1980s.<sup>45</sup> In Mr Black's case, however, it was recognised by 1985 that he had NANB Hepatitis, for which no treatment was then available.<sup>46</sup> There was also evidence of previous exposure to Hepatitis B but not of ongoing infection.<sup>47</sup>

**7.24** Mr Black had a bleed into the tibial muscles of his right leg in about April 1981. On review on 9 April 1981, the last previous episode reported was of bleeding into the renal tract while in America.<sup>48</sup> When he was seen for routine review in September 1984, there was mild crepitus (a 'crackling' sound) in his right knee, suggestive of some underlying arthritis. He also complained of occasional lower back pain. Clinical examination was not remarkable and his liver function tests were normal.<sup>49</sup> In December 1985, liver function test results were again significantly elevated.<sup>50</sup> Dr Colvin thought that it was difficult to make much of the increase, however, as fluctuating transaminase results are typical of NANB Hepatitis/Hepatitis C. Inflammation of the liver varies from time to time and it was necessary to look at a sequence of results to tell whether the patient truly had an increase in transaminases.<sup>51</sup>

**7.25** In 1987, Mr Black was in Fort Pierce, Florida. He was admitted to hospital there on 30 September complaining of black stools, generalised weakness and lethargy. He was given packed red cell support and cryoprecipitate. He had a Computerised Tomography (CT) scan which proved to be negative for retroperitoneal haematoma or any other intra-abdominal pathology.<sup>52</sup> Upper endoscopy revealed Grade 1 oesophageal varices.<sup>53</sup> This was the first significant episode of clinically apparent liver disease. Liver damage causes a build-up of pressure in the portal venous system which backs up into the stomach and oesophagus and causes internal varicose veins (oesophageal varices) to develop.<sup>54</sup> Though not specifically related to Hepatitis C, in that the condition can have other causes, oesophageal varices associated with liver damage are a frequent complication of cirrhosis.<sup>55</sup> The doctors in Fort Pierce apparently suggested to Mr Black that there was an underlying cause of the varices and that his liver damage was potentially virus-related.<sup>56</sup>

**7.26** On return to Scotland, Mr Black was admitted to the GRI in October 1987, where he gave an account of his experience in the USA. On examination, the US findings of varices were confirmed. Mr Black had an old Mallory-Weiss tear (scarring at the gastro-oesophageal junction), a condition usually associated with vomiting.<sup>57</sup> By 1987, the liver and spleen were palpable (noticeable to the touch in examination) and there was evidence of chronic liver disease.<sup>58</sup> Mr Black was informed that the virus could have caused his diseased liver to become cirrhotic.<sup>59</sup> Portal hypertension and the oesophageal varices

<sup>59</sup> Witness statement of Mrs Jean Black [PEN.001.0011] at 0012. As per statement by Counsel to the Inquiry (Day 2, page 70), Mrs Black confirmed that the word 'sclerosis' in paragraph 7 of her statement should be 'cirrhotic'.

were treated in a conventional way.<sup>60</sup> Injection sclerotherapy (injection of a hardening solution) was performed on the varices.<sup>61</sup>

**7.27** As noted in paragraph 17.23 above, the biochemical abnormalities found in December 1979 were typical of NANB Hepatitis/Hepatitis C infection. By 1987, Mr Black's condition had progressed: there were Grade 1 oesophageal varices, the liver and spleen were palpable and there was portal hypertension. Dr David Mutimer, Consultant Hepatologist, Queen Elizabeth Hospital, Birmingham, considered that it could be assumed that cirrhosis was present in 1987. Since Hepatitis C typically takes at least two decades to develop in a person infected when young, infection had probably been acquired by Mr Black in the 1960s.<sup>62</sup> Dr Mutimer's evidence is accepted.<sup>63</sup> Since his evidence was that it takes 'at least' two decades for the disease to develop, however, the beginning of the period within which transmission occurred remains uncertain.

### Source of infection

**7.28** No specific source of infection has been clearly demonstrated. In Dr Mutimer's experience, Mr Black's history was fairly typical of patients with haemophilia who acquired Hepatitis C at a fairly young age. After a long duration of infection, he developed severe liver damage with cirrhosis and portal hypertension.<sup>64</sup> Rates of progression to cirrhosis, decompensated cirrhosis, hepatocellular cancer and liver-related death are closely related to age at infection.<sup>65</sup>

**7.29** Since there were abnormal liver test results by 1979, and since cirrhosis was established by 1987, it is unlikely, but not impossible, that Mr Black was infected in the USA in 1970. He was then about 33 and at the lower end of the cohort of male patients at the highest risk of developing cirrhosis within 30 years.<sup>66</sup> Having regard to Dr Mutimer's evidence about the natural history of Hepatitis C, the period between 1970 and 1987 was probably too short to provide a reliable basis to infer that the infection was transmitted at this time. On the other hand, some 10% of patients do develop cirrhosis in 15 to 20 years and the possibility of infection in 1970 cannot be wholly excluded. Dr Mutimer's evidence more confidently excludes from responsibility for Mr Black's infection the use of Factor VIII concentrate in 1975 and 1978 and the use of cryoprecipitate in 1978 and later.

**7.30** There are three remaining possibilities: the use of blood and plasma up to the late 1950s, the single known infusion of AHG in 1965 and the cumulative use of cryoprecipitate up to the late 1960s. At the material time, AHG was prepared in Edinburgh from plasma pooled from small numbers of donors, limited by the processing capacity of the equipment available at the Royal Infirmary of Edinburgh (RIE). In 1965 the prevalence of Hepatitis C in the blood donor population is likely to have been relatively low and, statistically, the chances of an individual batch of AHG being infected were very low. In the absence of specific evidence it would be impossible to find positively that this procedure was the cause of Mr Black's infection. It might have transmitted infection, however: blood, plasma, AHG and cryoprecipitate were all capable of transmitting infection.

<sup>65</sup> Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraphs 13.68–13.69

<sup>66</sup> *Ibid* paragraph 13.71

**7.31** There was discussion of whether the continued use of cryoprecipitate in Mr Black's therapy in the period 1987–88 was appropriate.<sup>67</sup> Dr Colvin's evidence was that, at that time, to counter the risk of transmission of HIV, effective virus inactivation of factor concentrates had led to a change in recommended practice from the use of cryoprecipitate to the use of heat-treated concentrates. In 1986, when a test for HIV infection had become available, Mr Black had been tested and proved negative.<sup>68</sup> Dr Colvin's view was that, since Mr Black's liver function tests were already abnormal by the mid-1980s and Mr Black was HIV-negative, the use of cryoprecipitate after the introduction of virally inactivated large pool concentrates in the mid-1980s was clinically irrelevant to his case. That view is accepted.

**7.32** So far as is material, Dr Colvin thought that Mr Black had probably had enough single donor unit products to expose him to a high risk of having already contracted Hepatitis C before he was first treated with a large pool concentrate around 1975.<sup>69</sup>

**7.33** Dr Mutimer reviewed Mr Black's medical records. In his view, exposure to Hepatitis C was almost inevitable as a consequence of the treatment he received for haemophilia.<sup>70</sup> His view was similar to Dr Colvin's.<sup>71</sup> Mr Black had been treated with doses of single donor cryoprecipitate and with Factor VIII concentrate. The more bags or bottles of cryoprecipitate a patient received on a random basis, the greater the chance was that eventually the patient would receive a dose that was infected with Hepatitis C. Every time the patient was treated the risks were the same and, eventually, an infected unit would be transfused.

**7.34** In conclusion, Mr Black contracted Hepatitis C from infected blood products. For all practical purposes, infection with Hepatitis C was inevitable given the requirements of haemophilia therapy. Given the wide range of possible durations implicit in Dr Mutimer's evidence about the natural history of the disease, it is not now possible to be specific as to the source of infection. On balance, and on the evidence available to the Inquiry, the most likely source was therapeutic blood products administered in Scotland. It is highly likely that Mr Black was infected by NHS cryoprecipitate or concentrates, probably in the 1960s.<sup>72</sup>

### **Progress of infection**

**7.35** Mr Black was due to visit Kenya and Uganda in February 1986. He had a series of tests in advance and it was noted that his transaminases were markedly elevated at that time.<sup>73</sup> In November 1986 and August 1987 he had further dental treatment supported by cryoprecipitate.<sup>74</sup> On each occasion further treatment was required for post-extraction bleeding.

**7.36** At about this time Mr Black's health began to take a turn for the worse. As noted in paragraph 7.25 above, he was admitted to hospital in the USA on 30 September 1987. Beginning on 14 October 1987, after his return to Scotland, he had frequent and

<sup>74</sup> GRI Haemophilia Centre Treatment Sheet [BLA.001.2231]

substantial cryoprecipitate therapy for gastro-intestinal bleeding.<sup>75</sup> In March 1988, he was treated with SNBTS Factor VIII concentrate.<sup>76</sup> Home treatment with SNBTS Factor VIII was prescribed from January 1990 and amounted to 24,850 units in the course of the year.<sup>77</sup> Home treatment continued into 1991. By September 1991, the presumption of his clinicians was that Mr Black's varices were secondary to Hepatitis C as a consequence of the blood products he had received over the years for haemophilia.<sup>78</sup> On 14 October 1991, Mr Black was found to be positive for the antibody to Hepatitis C and that was confirmed by the RIBA-2 test.<sup>79</sup> In August 1992, Monoclate, a commercial Factor VIII product, was prescribed.<sup>80</sup> In 1993, he received further commercial concentrate, HP Factor VIII.<sup>81</sup> Mr Black was now being treated more frequently with factor concentrates.

**7.37** In March 1994 a referral was made for consideration of Interferon therapy for the treatment of Hepatitis C. There was extensive discussion and the consultant gastroenterologist, Dr J F MacKenzie, advised that therapy should be tried.<sup>82</sup> Dr Colvin thought it unlikely that treatment would have been effective, however.<sup>83</sup> Dr Mutimer agreed: Mr Black had already developed cirrhosis with evidence of decompensation. Interferon was the only therapy available and was unlikely to help under those circumstances. In retrospect, in all probability, had antiviral therapy been given, it 'would have caused significant morbidity and was unlikely to cure the infection'.<sup>84</sup> Therapy was not started, partly because Mr Black was reluctant to undergo treatment.<sup>85</sup> This was an early indication of Mr Black's attitude to therapy which he was to repeat in response to advice from time to time thereafter.

**7.38** In late spring 1994, Mr Black was again in the USA. While there, he developed gross ascites and pitting oedema (abnormal accumulations of fluid in body cavities), both due to salt and water retention and attributable to liver failure.<sup>86</sup> When back in Glasgow, he was told that he would not be well enough to travel to Italy two weeks' from then as he had intended.<sup>87</sup>

**7.39** On 6 April 1995, Dr MacKenzie reported to Professor Lowe that there had been a very slow deterioration in liver function and that Mr Black remained 'unkeen' on any medication. Dr MacKenzie suggested that a liver transplant might become an option within the next few years.<sup>88</sup> In May 1995, Dr MacKenzie raised the subject of transplant with Mr Black again. Following discussion, he referred the question whether early- or medium-term transplant would be appropriate, to Dr Alastair MacGilchrist at the Liver Transplant Unit (LTU), RIE, in a letter dated 22 May. Mr Black had indicated that he wanted to discuss the matter with Dr MacGilchrist.<sup>89</sup>

<sup>89</sup> Letter from GRI General Medicine to LTU RIE dated 22 May 1995 [BLA.001.0260]

**7.40** Dr MacGilchrist saw Mr Black and reported to Dr MacKenzie on 3 July 1995. His assessment was:

Reverend Black is a good candidate for liver transplantation. Clearly, it will be a major undertaking for the blood transfusion service to supply sufficient quantities of Factor 8 to cover the procedure, but this should not be a major problem and ... transplantation has been undertaken successfully with patients with haemophilia elsewhere.<sup>90</sup>

**7.41** Mr Black returned to the LTU in September 1995 and was seen by a registrar. He had been researching his condition on his own initiative but was finding it difficult to obtain statistics regarding haemophilia patients who had been transplanted. He was reported to be 'anxious and giving rather mixed messages'. The registrar's view was that he was 'terrified' that his condition was going to deteriorate suddenly to the extent that it would preclude transplantation. She had tried to emphasise to him that that was not the natural course of events and proposed that he should come in for assessment.<sup>91</sup> He agreed and in October/November an assessment was carried out over four days.<sup>92</sup> After comprehensive review by a multidisciplinary team, it was decided that his current liver function and quality of life were such that he did not require liver transplantation at that stage.<sup>93</sup>

### **The transplant and progression of disease**

**7.42** In 1996, Mr Black's liver function had deteriorated to the point at which transplantation was considered appropriate.<sup>94</sup> Arrangements were made for him to be admitted for assessment on 18 March.<sup>95</sup> A liver transplant was performed on 21 April 1996<sup>96</sup> and Mr Black was in hospital from 20 April until 13 May. After the operation there was some fluid retention and he was prescribed antibiotics for spontaneous bacterial peritonitis but, by the time of discharge, he looked well with no symptomatic pallor, jaundice or leg swelling. He was to be reviewed in May.<sup>97</sup> The family was encouraged to be optimistic. Mrs Black told the Inquiry, 'The projections at this time were that his new liver would last his lifetime before the Hepatitis C had the chance to affect it.'<sup>98</sup>

**7.43** One potentially important finding was made at this time. Mr Black's own explanted liver was sent for detailed pathological examination following the transplantation procedure where it was discovered that his cirrhosis had been complicated by the development of primary hepatocellular cancer.<sup>99</sup> The extent to which that information influenced, or did not influence, his medical care over the following period became the subject of investigation at a later stage and is referred to in paragraph 7.55 onwards below.

**7.44** After surgery in April 1996, Mr Black continued to be monitored. When he was reviewed on 24 October 1996 there was a discussion of his long-term prospects. The report from a registrar in the LTU to his GP noted that Mr Black was obviously quite an anxious man. He had enquired about the long-term impact of Hepatitis C recurrence and

<sup>97</sup> Discharge Letter from LTU RIE to GP dated 21 May 1996 [BLA.001.1422]

<sup>98</sup> Witness statement of Mrs Jean Black [PEN.001.0011] at 0014

<sup>99</sup> Pathology Result Enquiry Report dated 25 April 1996 [BLA.001.2289]; Dr Mutimer's report [BLA.001.2277]

the chances of developing cirrhosis. He was advised that the long-term prognosis was hard to predict, although it was reasonable to predict that his quality of life should be fairly good for the next 10 years.<sup>100</sup>

**7.45** Monitoring continued over the period from 1996 to 2002 and there were frequent discussions about the possibility of drug therapy for his ongoing Hepatitis C when Mr Black attended hospital. He remained uncertain, however. Dr MacGilchrist saw him on 11 December 1997. At that time he was keeping extremely well and working as hard as ever but his liver function tests were causing some concern. Those test results never returned completely to normal and, in particular, his ALT was quite significantly raised. Dr MacGilchrist thought that the results were most likely to represent recurrent hepatitis in his new liver. In order to avoid worrying him over the Christmas period, Mr Black was told only that his liver tests were slightly abnormal and that he should have a repeat test done by his GP in January 1998.<sup>101</sup>

**7.46** Mr Black was reviewed during 1998. In April, he was doing well and his liver function test results were slightly better.<sup>102</sup> In November 1998, however, his liver function test results were again causing concern.<sup>103</sup> When Mr Black was seen at the LTU in February 1999, matters had developed further. The report of the review to his GP stated:

He was informed that his liver biopsy showed recurrence of hepatitis C and that we would probably consider treating him for hepatitis C. He himself was not quite sure if that would be the best option for him at this present time as he felt that the side effects of Interferon would be too much for him. He agreed though to have an appointment with our hepatitis C team which will help discuss the options with him.<sup>104</sup>

**7.47** The review process continued in and after 1999. In June 1999 combination treatment with Interferon and Ribavirin was discussed with him but he remained rather reluctant to start it.<sup>105</sup> That continued to be his position for a period thereafter.

**7.48** In February 2001, Mr Black had a liver biopsy for further assessment of his Hepatitis C. Although he had earlier declined anti-viral therapy, consideration was again given to its commencement.<sup>106</sup>

**7.49** In April 2001, Dr Kenneth Simpson, LTU, had a long discussion with Mr Black about treatment. He commented in a letter to his GP that, with the introduction of combination Interferon and Ribavirin, treatment had improved and that Mr Black seemed much more receptive to the idea and had agreed to think about receiving treatment.<sup>107</sup> When he attended for review on 27 September 2001, Mr Black felt that he would be happier to wait before undertaking this therapy in view of the potential side-effects which he might find disruptive to his life. He was very busy at work.<sup>108</sup> Mr Black remained uncertain and Dr Mutimer thought that there was probably uncertainty on the side of the physicians as

<sup>107</sup> Letter from LTU RIE to GP dated 20 April 2001 [BLA.001.0117]

<sup>108</sup> Letter from LTU RIE to GP dated 16 October 2001 [BLA.001.0111]

well: they were aware that the treatment was associated with significant side-effects and that the chances of success were fairly low. He thought that the decision Mr Black took to decline treatment was quite understandable.<sup>109</sup>

**7.50** In early 2002, Mr Black's liver function test results continued to show elevated ALT levels.<sup>110</sup> His work commitments were heavy, however, and a decision to start treatment was again deferred. In April 2002 Mr Black had an ultrasound scan with satisfactory results.<sup>111</sup> Liver biopsy revealed Hepatitis C virus fibrosis in the transplanted liver, short of cirrhosis but thought to be more advanced compared to the year before.<sup>112</sup>

**7.51** When seen in April 2002, Mr Black said that he might be more amenable to treatment as he was reducing his workload.<sup>113</sup> By that stage he had been told of dual therapy and the improved prospects of success it offered. He was seen by Dr Simpson on 8 August 2002. The diagnosis recorded in a letter to his GP and copied to other clinicians listed the transplant, previous haemophilia and recurrent Hepatitis C with significant fibrosis on liver biopsy.<sup>114</sup> On this occasion Mrs Black was at the review. The letter stated:

I had a long chat with Rev Black about the possibility of treatment, the conversation I had had with him previously. Certainly his liver biopsies have clearly demonstrated progressive fibrosis, and without attempting anti-viral treatment it is clear that he will develop recurrent cirrhosis. He again seemed quite keen in the clinic to start anti-viral treatment ....<sup>115</sup>

**7.52** In December 2002, Mr Black commenced treatment with pegylated Interferon and Ribavirin.<sup>116</sup> By then fibrosis was more advanced. The anti-viral treatment did not run smoothly.<sup>117</sup> He experienced anaemia severe enough to necessitate a transfusion.<sup>118</sup> The treatment was abandoned.<sup>119</sup>

**7.53** Dr Mutimer said:

The problem with the anaemia is due to the ribavirin component of his treatment, and the main problem is that the dose needs to be adjusted very carefully and frequently in patients if they have any degree of kidney dysfunction, which is quite common in the transplant patient. So I suspect the severe anaemia was because the level of the ribavirin was too high for the patient. But there are no useful published guidelines on picking the right dose.<sup>120</sup>

**7.54** In May 2003, Mr Black was admitted for ultrasound-guided liver biopsy. Scans had suggested a possible focal lesion. Two cores of tissue were taken and pathology confirmed hepatocellular carcinoma.<sup>121</sup> Dr Andrew Bathgate, by then a consultant physician at the LTU, told Mr Black that this had happened, and that it was clear from the imaging that

<sup>121</sup> Letter from LTU RIE to GP dated 4 June 2003 [BLA.001.0079]

the cancer was multifocal.<sup>122</sup> The cancer had spread, probably with multiple nodules throughout the liver.<sup>123</sup> It could not be treated.<sup>124</sup> Mr Black died on 31 October 2003.<sup>125</sup>

### **Hepatocellular cancer in the explanted liver: Mr Black's management as a patient**

**7.55** As noted in paragraph 7.43, Mr Black's pathology records revealed that the liver removed at the time of the transplant in 1996 was cancerous. Mrs Black said that it had come as a shock to the family to learn that Mr Black's own liver had been affected by cancer. She said that Mr Black was not aware of that fact and that the family was not aware either. Having regard to the evidence as a whole, including the retrospective investigations carried out by Dr MacGilchrist and comment by Dr Bathgate, it is clear that Mr Black was not told of the hepatocellular cancer in the explanted liver. The discharge letter sent to Mr Black's GP made no mention of any tumours.<sup>126</sup> Consequently, other than in relation to a communication dated 22 December 1998 (see paragraph 7.63 below) there is nothing to suggest that the GP knew of the finding.

**7.56** The full findings relating to the explanted liver were recorded in a pathology report dated 25 April 1996.<sup>127</sup> The external appearance was reported to be that of a macronodular cirrhotic liver showing a number of nodules of varying sizes. On section, the left lobe was found to contain a tumour mass of at least 4 x 3 x 3cm showing areas of necrosis as well as a large cystic necrotic cavity 2cm in diameter and a number of adjacent separate nodules, some of which showed necrosis. A separate nodule 2cm in diameter also displayed extensive necrosis. Throughout the right lobe there were several nodules that did not show significant necrosis but one, 2.5cm in diameter, showed extensive necrosis. In a summary of micro-examination it was noted that there were at least five separate nodules showing features of hepatocellular carcinoma on the left lobe and a further three tumours on the right lobe.

**7.57** Following his transplant surgery, Mr Black was transferred to the main ward of the LTU on 22 April 1996.<sup>128</sup> Apart from a weekend at home, he remained in hospital until 13 May.<sup>129</sup> During that time, his In-Patient Clinical Notes did not refer to cancer in the explanted liver. The letter sent to Mr Black's GP after review on 29 May 1996, noted as diagnosis: 'liver transplant for Hepatitis C related cirrhosis and Haemophilia A'.<sup>130</sup> On 17 June Mr Black returned to hospital when his notes recorded three diagnoses: Haemophilia A, Hepatitis C cirrhosis and that Mr Black was cytomegalovirus positive. In a side note it recorded: '(incidental HCC at op)' without further detail.<sup>131</sup>

**7.58** The detailed pathology report dated 25 April 1996 was not in the copy of the hospital records originally recovered by the Inquiry from the Crown Office. On 17 December 2010, the Central Legal Office wrote to the Inquiry with the information that an unnamed

<sup>129</sup> Discharge letter from LTU RIE to GP dated 21 May 1996 [BLA.001.1422]; LTU RIE Clinical Notes dated 2 to 6 May 1996 [BLA.001.1764]

<sup>130</sup> Letter from LTU RIE to GP dated 5 June 1996 [BLA.001.1637]

<sup>131</sup> In-Patient Clinical Notes [BLA.001.1768] 'HCC' is a standard abbreviation for hepatocellular cancer.

haemophilia clinician had noted that a pathology report did not appear to be included in the records. With the letter were enclosed copies of a number of reports including a copy of the report dated 25 April 1996. The copy,<sup>132</sup> which appeared to be a print of an electronic record, was thereafter used during the Oral Hearings.

**7.59** Copies of the records of the LTU came to hand after the completion of the Oral Hearings. The original paper records had been scanned on 13 August 2012 and then destroyed. The LTU retains patients' records in electronic form in its TRAK record system and routinely destroys paper records. Electronic and hard copy prints of Mr Black's LTU records were sent to the Inquiry on 16 August 2013. They contained a further copy of the pathology report of 25 April which was initialled by Dr Bathgate, showing that the report had been received from pathology and entered the LTU records for Mr Black. The precise date when that occurred is not known but it was probably entered around the date it bears. Dr Bathgate explained in a letter dated 13 December 2013 that, at that time, written reports of explant pathology were routinely sent to the LTU doctors' room.<sup>133</sup> The transplant registrar was responsible for signing all laboratory reports before they were filed in the paper records of the LTU. The reports were reviewed at meetings of the consultant hepatologists and gastroenterology registrars held on Mondays at lunchtime. At the time it was not LTU practice to discuss explant pathology with patients while they were recovering from surgery. That remains the practice at present.

**7.60** It is clear from the evidence, and in particular from Dr Bathgate's letter, that the report of 25 April 1996 which he initialled as transplant registrar was at all material times contained in the paper and electronic records of the LTU relating to Mr Black and available to the clinical team looking after his interests from time to time. Dr Bathgate ceased to be transplant registrar at the end of April 1996. He was replaced by Dr Khalid Bzeizi.

**7.61** As already indicated, Mr Black was reviewed regularly at the LTU between May 1996 and July 1998. Letters to his GP reporting his progress frequently noted as his diagnosis as liver transplant for Hepatitis C, related cirrhosis and Haemophilia A. His history of hepatocellular carcinoma and the risk of recurrence were not mentioned.

**7.62** So far as the Inquiry has been able to discover, the next reference to the condition of the explanted liver after June 1996, was in December 1998. The clinical notes for 9 December said that Mr Black had been admitted for liver biopsy, noting abnormal LFTs and 'HCC recurrence'.<sup>134</sup> An explanatory note stated: 'Liver transplant for HCV cirrhosis 1996 Apr incidental HCC at operation', effectively repeating the note made on 17 June 1996. A subsequent note on the same day commented: 'note incidental HCC at OLT – (P) USS today + biopsy at that time ...'.<sup>135</sup> The reason for this procedure was Mr Black's continually raised liver function test scores.<sup>136</sup> On 10 December, it was reported that radiology and ultrasound scanning found no focal lesion.<sup>137</sup> Liver biopsy was performed and the provisional report showed changes compatible with recurrent Hepatitis C.<sup>138</sup>

<sup>132</sup> Copy of Report [BLA.001.2289]

<sup>133</sup> Dr Bathgate's letter to the CLO dated 13 December 2013 [PEN.019.1446]

<sup>134</sup> In Patient Clinical Notes (Surgical) [BLA.001.1773]

<sup>135</sup> In Patient Clinical Notes (Surgical) [BLA.001.1774]; 'OLT' and '(P) USS' are understood respectively to be abbreviations for 'Orthotopic Liver Transplant' and 'Planned Ultrasound Scan'.

<sup>136</sup> Letter dated 12 November 1998 from LTU RIE to GP [BLA.001.1583] at 1584

<sup>137</sup> In Patient Clinical Notes (Surgical) [BLA.001.1774]

<sup>138</sup> Letter from RIE to GP dated 22 December 1998 [BLA.001.1436]

**7.63** The discharge letter following these procedures, dated 22 December 1998 and sent to Mr Black's GP, listed under 'Diagnosis':

1. Liver transplant for hepatitis C cirrhosis – April 1996
2. Five small HCC in explanted liver (undiagnosed pre transplant)
3. Previous haemophilia
4. Abnormal liver function tests secondary to recurrent hepatitis C.<sup>139</sup>

**7.64** Although the second item in the list did not accurately reflect the information contained in the pathology report of 25 April 1996, it notified the GP that there had been cancer in the explanted liver.

**7.65** With the exception of the (inaccurate) 'Diagnosis' in the letter of 22 December 1998, hepatocellular cancer was not mentioned in the letters sent to Mr Black's GP, nor does it appear as an issue in the records up to that point, with the exception of the entries of 9 December 1998. There is nothing to suggest that the understanding reflected in the letter of 22 December was treated as significant.

**7.66** Mr Black showed an interest in his risk of cancer in general. For example, in November 1998, when he was seen at the LTU,<sup>140</sup> he was concerned about spots on his forehead and neck because he had previously had malignant spots removed from his back. He was referred to a dermatologist to exclude the possibility of malignancy; in the event, Mr Black required minor surgery for the removal of two basal cell carcinomas. The dermatologist's history noted previous Haemophilia A and Hepatitis C infection at liver transplant in 1996 only<sup>141</sup> and there is no evidence that the dermatologist was aware of the cancer in Mr Black's explanted liver: there was no reference to it in the records of the dermatologist's examination of Mr Black. If Mr Black had known of his previous hepatocellular cancer, he might have discussed it with the dermatologist examining the spots for malignancy. If that had been recorded, it would have been significant. It might not have been recorded even if Mr Black did mention it, however, and little turns on the absence of any record.

**7.67** Mr Black continued to be monitored. He was reviewed at the LTU in February 1999. The letter following this review, in common with other letters from the Unit up until this time (with the exception of the letter of 22 December 1998), set out the diagnosis as follows:

1. Liver transplant for hepatitis C cirrhosis – April 1996
2. Previous haemophilia
3. Abnormal liver function tests, recurrence of hepatitis C.

**7.68** There was again no reference to hepatocellular cancer in the explanted liver.<sup>142</sup>

**7.69** With one exception, the hospital reports continued in the same way until cancer was again diagnosed in the liver in 2003.<sup>143</sup> A record sheet dated 13 March 2002 of what appears to have been part of a research exercise, had commented: 'HCCs found in removed patient's liver' without further comment.<sup>144</sup> Other records from the same date contain no similar reference.

<sup>139</sup> Ibid [BLA.001.1436]

<sup>140</sup> Letter from Transplant Coordinator RIE to GP dated 12 November 1998 [BLA.001.1438]

<sup>141</sup> In Patient Clinical Note dated 8 December 1998 [BLA.001.1775]

<sup>142</sup> Letter from locum lecturer LTU RIE to GP dated 16 February 1999 [BLA.001.1416]

<sup>143</sup> Letter from specialist registrar to GP dated 4 June 2003 [BLA.001.0079]

<sup>144</sup> Record Sheet [BLA.001.1430]

**7.70** In 1996, routine pre-operative imaging for transplant assessment in Edinburgh involved ultrasound scanning of the liver.<sup>145</sup> Ultrasound examinations in 1994 and 1995 reported that there were no focal lesions or masses. Ultrasound examination on 2 November 1995 showed a 'very shrunken cirrhotic liver', but 'nil focal'.<sup>146</sup> The policy in 1996, where hepatocellular cancer was recognised prior to transplant or discovered in the explanted liver, was to continue ultrasound scans and measurement of serum alpha fetoprotein every six months after transplant.<sup>147</sup> The records show that serum alpha fetoprotein was regularly monitored in Mr Black's case. Ultrasound examinations of the liver graft were also recorded. It would not, however, be possible to infer that these steps were taken in pursuit of the protocol described or that they implied actual knowledge of the cancer in the explanted liver. Mr Black was seen much more frequently than the protocol required and this issue was not raised.

**7.71** The Inquiry asked Dr MacGilchrist to investigate the medical records in an attempt to explain the omission from them of a full record relating to the pathology in Mr Black's management. He did not discover an explanation. He reported on his review of the records on 1 March 2011.<sup>148</sup> Dr MacGilchrist speculated that the finding was somehow overlooked, which would explain why it was not discussed with Mr Black's family and, by implication, with Mr Black himself. In his report Dr MacGilchrist apologised to Mr Black's family for any distress caused by the disclosure of the existence of cancer in the explanted liver. It is clear from the report that he would have expected the discovery of such an extensive multifocal carcinoma as in Mr Black's case to have been discussed with the patient at the time. Dr Mutimer said that this was information that should have been shared with the patient.<sup>149</sup> That was not done.

**7.72** In answer to Mr Anderson, counsel representing NHS interests, Dr Mutimer dealt with the suggestion that there might have been no benefit in telling Mr Black, who was clearly an anxious man:

I think it is honesty really. It is providing the patient with information that will be of interest to him and it may actually determine his attitude to his illness and his recovery. So I think it's appropriate to discuss it with him. You are quite right that it may have unfortunate consequences in causing anxiety and the cancer may never recur, in which case in retrospect you might look back and say, "I wish we had never told him," but I don't think we are in a position to manage patients like that. This is important information that should have been shared with the patient ....

I think there are circumstances in medicine where it might be suggested that it is in everyone's interest, including the patient's, for information to be withheld, but I don't see that in this case.<sup>150</sup>

**7.73** The discharge letter of 21 May 1996 sent to Mr Black's GP should have included reference to the cancerous tumours. Mr Black's subsequent management ought to have

---

<sup>145</sup> Dr MacGilchrist's report [PEN.013.1091] at 1092

<sup>146</sup> Clinical Record [BLA.001.1737]. 'Nil focal' indicates that no tumour was identified.

<sup>147</sup> Dr MacGilchrist's report [PEN.013.1091] at 1092. Alpha fetoprotein is the major protein found in fetal serum (the blood of unborn children). Usually undetectable after birth, its detectable presence in adult blood is a sign of hepatocellular carcinoma.

<sup>148</sup> Dr MacGilchrist's report [PEN.013.1091]

<sup>149</sup> Day 2, page 147

<sup>150</sup> Ibid pages 153–154

been informed by the findings from the explant pathology report and steps should have been taken to ensure that Mr Black was aware of them. Notwithstanding Dr MacGilchrist's research and the Inquiry's investigations, no evidence has been uncovered that might explain the omission to discuss the report. It appears that the pathology report was overlooked throughout the relevant period, as Dr MacGilchrist and Dr Bathgate suggested. That would be consistent with the clinical notes and correspondence in the medical records.

**7.74** Mr Black was seen by consultants following the rota system in operation. That system has considerable advantages for patients, who are assured of regular attention from senior staff, which would be less easy and perhaps impossible to secure if the patient was under the exclusive attention of a single individual.

**7.75** So far as the Inquiry is aware, the omission to inform Mr Black of the cancer in his explanted liver was a unique lapse. With the exception of the group discussions, the records of the LTU were comprehensive. There was no lapse in record keeping. The failure related to the use of the records available. Responsibility for the RIE at the time lay with the Royal Infirmary of Edinburgh National Health Service Trust and now lies with the Lothian Health Board. Standard protocols for the preparation of records of team discussion appear to be management matters for the Board.

### **Treatment for Hepatitis C**

**7.76** The procedure of liver transplantation 'cured' Mr Black's haemophilia because the transplanted liver produced Factor VIII. Reinfection of the liver with Hepatitis C was inevitable, however.<sup>151</sup> The Hepatitis C virus would not have been cleared by the transplant procedure and the new liver was vulnerable to infection. Further, treatment was not without complications and there was a low level of success.

**7.77** Dr Mutimer said in his report:

According to the records, the possibility of antiviral therapy was discussed with the patient on a number of occasions during 1999, 2000, 2001 and 2002. At that time, there were few published data to encourage the use of antiviral therapy for Hepatitis C after transplantation. It was recognised that the results of Interferon treatment were poor with very few patients cured. In addition, it was recognised that Interferon was associated with significant side effects and that treatment could precipitate rejection of the transplanted liver.

[T]he year 1997 saw the first report of combination antiviral therapy for transplanted patients .... Compared with Interferon alone, it appeared that the combination therapy was more likely to be successful ....

Between 1997 and 2002, the peer-reviewed medical literature included approximately 10 small reports that described the results of combination antiviral therapy. The average cure rate in those reports was less than 20%. Therefore, the results of treatment were still disappointing and side effects were significant ....<sup>152</sup>

---

<sup>151</sup> Dr Colvin's report [BLA.001.2281] at 2285

<sup>152</sup> Dr Mutimer's report [BLA.001.2277] at 2278–2279

**7.78** Dr Mutimer thought that the decision Mr Black took to decline treatment up to December 2002 was quite understandable.<sup>153</sup>

**7.79** It must remain a matter for speculation how Mr Black might have responded to information about the cancer in his own liver. It might have influenced him, especially if he was informed about the risk of recurrence of cancer in the transplanted liver, and made him more receptive at an earlier stage to proposals that he should have treatment after his liver transplant in 1996. In general, it is clear from the evidence of Dr Mutimer in particular that Mr Black was entitled to have all information that might have had a bearing on his attitude to treatment.<sup>154</sup> It is not possible to form a view on whether a different course of management would have been adopted, but that might have happened if Mr Black had been fully informed.

### **Consequences of not detecting cancer pre-transplant**

**7.80** As events turned out, the fact that cancer was not detected in Mr Black's own liver before the transplant in 1996 was not altogether to his disadvantage. Dr Mutimer summarised the position disclosed in the pathology reports from 1996.<sup>155</sup> The explanted liver showed extensive primary liver cancer, as already narrated.

**7.81** In view of the size of the largest tumour, 4 x 3 x 3cm, it might have been expected that it would have been seen on imaging before the transplant operation. That did not happen. The chance of discovery depended on the procedures followed and on the equipment available at the time. Ultrasound examination of the liver was routine in pre-transplant imaging assessment in Edinburgh in 1996 but that technology might have failed to detect even the extensive and numerous tumours found in the explant. Subsequently, more advanced imaging techniques became available and, had they been available in 1996, the lesions may well have been detected.<sup>156</sup>

**7.82** Had Mr Black's cancer been discovered pre-transplant, and follow-up investigations carried out which disclosed tumours of the number and size involved in both the left and right lobes of the liver, it is likely that Mr Black would have been considered unsuitable for transplant. Dr MacGilchrist concurred with Dr Mutimer's view that the risk of tumour recurrence was proportional to the size and number of tumours in the liver and commented that only patients with a limited size and number of tumour nodules were considered suitable for transplant.<sup>157</sup>

**7.83** The transplant was carried out, however, and that prolonged Mr Black's life. It also created the context for later developments, and for the question that now arises.

### **Recurrent or new tumour?**

**7.84** If, as was to happen, Mr Black did have a transplant and cancer developed in the new graft, there would be two possibilities: either this would be a recurrence of the original tumour or development of new tumour in the transplanted liver. That issue arose for discussion among senior clinicians when cancer in Mr Black's liver was next diagnosed in 2003. It was seven years after transplant and an unusual development. Dr MacGilchrist

<sup>155</sup> Supplementary Report [BLA.001.2287] at 2288

<sup>156</sup> Mr MacGilchrist's report [PEN.013.1091] at 1092

<sup>157</sup> Ibid [PEN.013.1091] at 1092

agreed with the conclusion reached at the time: that it was most likely to be a new tumour rather than a recurrence.<sup>158</sup>

**7.85** Dr Mutimer thought, as did Dr MacGilchrist, that having regard to the number and the size of the tumours in the explanted liver, there had been a significant risk of recurrence in Mr Black's case. On the other hand, seven years was an unusually long period before recurrence: it was usually found within two years. He had hardly ever encountered a period as long as five years. The length of the period did not completely resolve the question whether this was a recurrence or a new cancer, however. Dr Mutimer was reminded during his oral testimony that the annual ultrasound examination in 2002 showed no evidence of cancer.<sup>159</sup> He said that indicated that any cancer, if present, was extremely small, probably less than one centimetre in size but that possibly the cancer had not yet developed.<sup>160</sup> In his view, post mortem findings did not indicate whether the cancer represented recurrent cancer or a new cancer in the graft.<sup>161</sup>

**7.86** Dr Mutimer said:

I think that when transplantation is undertaken in the presence of cancer, we know that there is a proportion of cases where the cancer will recur following transplantation and there are no established strategies which will prevent that and, once recurrence does occur, if it is recurrence, then there are no proven therapies to prolong life ....

[T]he other possibility [is] that this is a new tumour. We know that when there is cirrhosis, there is a risk for cancer, and cirrhosis had developed in the graft, so it is possible that the cancer arose merely in the graft rather than representing cancer which had been lurking for seven years and then recurred as a form of recurrent cancer.<sup>162</sup>

**7.87** Dr Mutimer thought that forensic pathologists might have or be able to develop techniques for differentiating the possibilities.<sup>163</sup> The known techniques involved ascertaining the gender of the tumour and comparing it with the sex of the recipient. In this case, if the tumour was female, then the tumour would definitely be of donor origin. If the donor had been male, however, that avenue of investigation would not be open. In this case the donor was male.<sup>164</sup> It seemed that further exploration of developing technology would not have assisted the Inquiry in resolving the issues raised by the Terms of Reference and that the researches that he suggested as possibilities would not have been a worthwhile exercise in this case.

**7.88** If the fatal cancer was a recurrence, Dr MacGilchrist's view was substantially the same as Dr Mutimer's: if the patient is unlucky enough to develop a recurrent tumour, it is almost invariably incurable.<sup>165</sup> If Mr Black's tumour was a recurrence of the cancer in the explanted liver, nothing could have been done to prevent that and there would have been no reasonable possibility of successful treatment of that tumour.

<sup>164</sup> Dr MacGilchrist's report [PEN.013.1091]

<sup>165</sup> Ibid [PEN.013.1091] at 1092

**7.89** The alternative hypothesis which, on balance, appears to be more likely on the expert evidence as a whole, is that this was a new tumour. That was the view of Dr MacGilchrist<sup>166</sup> and his colleagues, and it is consistent with Dr Mutimer's observations on the likelihood of recurrence of the original tumour.<sup>167</sup> In that event, it was Dr Mutimer's view that:

Antiviral therapy if given successfully during the early years after transplantation may have prevented the development of graft cirrhosis. If his hepatocellular carcinoma represented *de novo* cancer in the graft, then the prevention of cirrhosis by antiviral therapy may have prevented the development of cancer.<sup>168</sup>

**7.90** As set out above, the possibility of antiviral treatment was discussed with Mr Black after his transplant when he attended hospital. He eventually began treatment in December 2002, by which time cirrhosis was established in the graft: it was, by that stage, too late.

**7.91** However, on the hypothesis that it was a new tumour, Mr Black's prospects might have been improved by treatment with antiviral therapy commenced soon after transplant and before cirrhosis developed. If he had been made aware of the cancer in his explanted liver then, faced with advice about the benefits of antiviral treatment in avoiding or arresting the progression to cirrhosis, either from the outset, or at least when successful dual antiviral therapy became available, it is possible that Mr Black would have been inclined to take the advice tendered that he should undergo treatment after transplant sooner rather than later and that he should persist with it. It was Dr Mutimer's view that, if it was a new tumour, prevention of the progression to cirrhosis with successful antiviral therapy would probably have prevented a new tumour from developing. However, his opinion was that successful antiviral treatment, or cure, occurred in less than 20% of patients after transplant.<sup>169</sup> It is impossible to say that there was any actual disadvantage from failure to inform Mr Black: by late 2002, when dual treatment started, he tolerated it very badly and he may not have tolerated treatment at any stage. Further, it is possible that by the time dual treatment was available he had developed cirrhosis again. At most there was a possible, if remote, chance of improvement of his prospects.

**7.92** As noted above (paragraph 7.81), it was the policy in 1996, where incidental hepatocellular cancer was discovered in an explanted liver, for continuing ultrasound scans to be performed and for monitoring of serum alpha fetoprotein to continue on a prescribed basis. These procedures were aimed at identifying possible tumour recurrence post transplant. Although not conforming to the protocol at the time, Mr Black did have these tests carried out and, as late as 2002, ultrasound showed no tumour. In the circumstances, he was not prejudiced by missing the chance of regular screening and, with it, possible detection of a tumour, by standard protocol monitoring.

**7.93** Leaving aside these possibilities, there was no criticism of Mr Black's management as a patient. Mr Black was one of the first patients with haemophilia to receive a transplant in the UK. The procedure was a remarkable success in giving him a prolonged life. He survived for seven years from liver transplant and had more than five years of good quality life.

---

<sup>166</sup> Ibid [PEN.013.1091] at 1093

<sup>167</sup> Dr Mutimer's supplementary report [BLA.001.2287] at 2288

<sup>168</sup> Dr Mutimer's report [BLA.001.2277] at 2279

<sup>169</sup> Ibid [BLA.001.2277] at 2278

**7.94** Dr Mutimer did not think that alternative management strategies following transplant could have changed the eventual outcome.<sup>170</sup> His conclusions were that:

- Detection of the extent of the tumour in the explanted liver in 1996 would not have altered management of Mr Black's disease in 1996 immediately after the transplantation.
- In the interval between 1996 and 2003, knowledge that there was cancer in the explanted liver would not have made any difference in his management following transplantation.<sup>171</sup>

**7.95** It was Dr Mutimer's opinion that the failure to inform did not impact on Mr Black's medical treatment which was at all times appropriate and that his treatment was beneficial. His opinion has a material bearing on the assessment of the chance that Mr Black might have had a better outcome had he been informed of his previous cancer and elected to receive treatment earlier.

**7.96** With the exception of the failure to provide information, Dr Mutimer had no concerns at all about the treatment given to Mr Black. From the time that Mr Black developed complications of liver disease, his medical management in Glasgow and Edinburgh seemed to him to be entirely appropriate.<sup>172</sup> Dr Colvin found no evidence of unreasonable or inappropriate treatment in this case.<sup>173</sup> These views are accepted, subject to the qualifications that necessarily arise from the failure to disclose the finding of cancer in the explanted liver.

### **Cause of death**

**7.97** The death certificate listed four conditions as contributing to Mr Black's death. In reverse order these charted the course of events chronologically: Mr Black suffered from haemophilia, which led to the transfusion of blood products, which caused Hepatitis C, which caused hepatocellular carcinoma in his transplanted liver.<sup>174</sup>

**7.98** As matters transpired, there was no doubt about the cause of death in Mr Black's case. The final development of hepatocellular carcinoma was a direct result of cirrhosis caused by Hepatitis C infection, whether the cancer was a recurrence of the original tumour or was a new tumour in the transplanted liver. Mr Black had mild to moderate Haemophilia A which was appropriately treated with cryoprecipitate and Factor VIII concentrates, prior to the development of virus inactivation for Factor VIII concentrates in the mid-1980s. Infection with Hepatitis C in Mr Black's case was not avoidable and, before the introduction of pegylated Interferon and Ribavirin, specific antiviral therapy for Hepatitis C was generally ineffective. It was not surprising that the transplanted liver became infected and cirrhotic or that a hepatocellular carcinoma developed. It is a matter of agreement on the part of Mrs Black and other 'patient interest' Core Participants that there were no reasonable precautions whereby death might have been avoided and that is clearly the case.<sup>175</sup>

## Conclusions

**7.99** Factors contributing to the death of Mr Black were:

(i) Mr Black's death on 31 October 2003 was due to Hepatitis C infection in the transplanted liver, originally transmitted by blood products, together with hepatocellular carcinoma.

**7.100** Infection with Hepatitis C:

(ii) Infection was inevitable given Mr Black's requirements for factor replacement therapy.

(iii) On the balance of probabilities Mr Black acquired Hepatitis C infection before the end of the 1960s in the course of haemophilia therapy in Scotland.

**7.101** Progression of disease following transplant:

(iv) With the development of hepatocellular carcinoma in the transplanted liver, there were no reasonable precautions that might have avoided death.

(v) It is impossible to form a firm conclusion on whether the fatal tumour was a new tumour rather than recurrence of the tumour in his explanted liver but, on balance, having regard to the expert evidence as a whole, the cancer which developed in Mr Black's liver graft was likely to have been a new tumour.

(vi) Antiviral therapy, if successful, during the early years after transplant might possibly have prevented or postponed the development of graft cirrhosis.

(vii) Prevention or postponement of progression to cirrhosis through antiviral therapy might possibly have prevented or significantly postponed development of a new tumour.

(viii) It is not possible to form a view whether earlier antiviral treatment would have been successful. It is no more than a possibility – estimated generally by Dr Mutimer to be less than 20%. Mr Black's lack of tolerance of treatment from December 2002 lengthened the odds against his ability to tolerate the necessary full course of antiviral treatment whenever attempted.

**7.102** Mr Black's management as a patient:

(ix) Mr Black was not told that there had been cancer in his explanted liver. Appropriate steps should have been taken to ensure that he was aware of the relevant explant findings in the pathology report. Failure to inform him was a lapse from acceptable standards of patient management.

(x) This lapse was not evidence of systemic failure. On the evidence available it was a unique occurrence.

(xi) Mr Black was entitled to have information on all relevant factors in considering whether to undergo antiviral treatment of his recurrent Hepatitis C infection. The history of hepatocellular carcinoma in the explanted liver may have influenced his decisions from 1996 and more particularly from December 1998, had he been aware of it.

(xii) Failure to inform Mr Black of the cancer in the explanted liver deprived him of the chance, however remote, of a longer life that might have followed successful earlier antiviral treatment and eradication of Hepatitis C.

(xiii) With that one exception Mr Black's management as a patient was at all times appropriate and of a high standard and reasonably related to his needs.

## Eileen O'Hara

**7.103** Mrs O'Hara was born on 9 October 1930. She was employed as an orderly at Stobhill Hospital from about 1980 to 1990 when she retired at age 60.<sup>176</sup> She died on 7 May 2003. The certified causes of death were:

- I (a) Hepatic Failure
- I (b) Septic Shock
- II Mitral Valve Disease.<sup>177</sup>

## Mrs O'Hara's medical history to July 1995

**7.104** Mrs O'Hara had a complicated medical history, starting in about 1963, involving cardiac, obstetric and gynaecological problems.<sup>178</sup> It is highly likely that the significant events that may have exposed her to transmission of the Hepatitis C virus happened before November 1990.

**7.105** On 11 January 1963, Mrs O'Hara had surgery for mitral stenosis (narrowing of the mitral valve of the heart).<sup>179</sup> The background to that condition was rheumatic heart disease: Mrs O'Hara had rheumatic fever as a child, probably in the late 1930s or early 1940s.<sup>180</sup> It was a common disorder in Scotland up to the late 1940s. With its origin in streptococcal infection, until penicillin became widely available, after about 1945, there was no effective treatment for the infection. Additionally, without the benefit of antibiotic treatment in childhood, the patient often presented later with the heart manifestations of rheumatic fever which specifically affected the heart valves, often leading to stenosis.<sup>181</sup>

**7.106** In early 1963, bypass procedure during surgery had not been introduced.<sup>182</sup> Treatment for mitral stenosis involved adjustment of the valve by manual valvotomy.<sup>183</sup> In this procedure, the chest was opened, usually under the left breast. A vent was inserted and the surgeon used his fingers to enter the left atrium of the heart and widen the mitral valve.<sup>184</sup> It was a skilful, but quite brief, operation and frequently it did not require transfusion. The available records did not resolve the question of whether Mrs O'Hara had received a transfusion in 1963 but left it open as a possibility. However, in November 1971 Mrs O'Hara was seen at the obstetrics department of Stobhill Hospital.<sup>185</sup> Her mitral valve disease was noted and it was recorded at that time that she had previously had a blood transfusion. While the source of that information was not disclosed, it suggests that it is highly likely that Mrs O'Hara did have a blood transfusion at the time of her surgery in January 1963.

**7.107** In March 1972, Mrs O'Hara received a blood transfusion on the birth of her son by Caesarean section.<sup>186</sup> Two bottles of whole blood were issued, of which one, numbered 5209, was transfused.<sup>187</sup> Subsequent research by the SNBTS has shown that the blood was

donated at Lockerbie on 5 March 1972.<sup>188</sup> There was no test for non-A, non-B Hepatitis/Hepatitis C in existence at that time.<sup>189</sup> There is no record of the donor having been subsequently tested for Hepatitis C.<sup>190</sup>

**7.108** On 28 November 1979, Mrs O'Hara had a hysterectomy at Stobhill. She received one unit of whole blood and one unit of packed cells in the course of the procedure.<sup>191</sup> Subsequent SNBTS research again traced the donations, to Coatbridge and East Kilbride, in November 1979. There was no record of either donor having been tested for Hepatitis C at any time.<sup>192</sup>

**7.109** In February 1984, Mrs O'Hara was seen in the medical out-patient clinic at Stobhill by Dr Francis Dunn, Consultant Cardiologist.<sup>193</sup> The main focus was heart disease. It was noted that liver function tests (LFTs) were abnormal and it was suggested that this might be a consequence of her mitral valve disease: patients with mitral valve disease likely to require surgery were also likely to have mild abnormalities of liver function.<sup>194</sup> At that stage, before successful replacement of her mitral valve, Mrs O'Hara had significant heart failure; pressure on the right side of her heart was significantly elevated in 1985 and that would have given rise to back pressure on the liver, leading to abnormal LFTs.<sup>195</sup> That was a reasonable view at the time according to Dr David Mutimer, Consultant Hepatologist at the Queen Elizabeth Hospital, Birmingham, who provided expert evidence to the Inquiry.<sup>196</sup> It could not have been concluded by her doctors before that date that she had acquired a chronic liver disease.

**7.110** In June 1985, Mrs O'Hara had cardiac surgery at the Glasgow Royal Infirmary (GRI). On that occasion a Wessex porcine bioprosthetic valve was inserted.<sup>197</sup> On 5 June, five packs of concentrated red cells were issued prior to surgery on 7 June.<sup>198</sup> All five were used.<sup>199</sup> Plasma was also administered.<sup>200</sup> The SNBTS was not able to trace the donors.<sup>201</sup>

**7.111** In early 1990, Mrs O'Hara was found to have diabetes mellitus.<sup>202</sup> Although her diabetes was initially controlled by diet, on 7 March 1990 her GP referred her to Stobhill Ophthalmology after an optician reported having found some signs of diabetic retinopathy (damage to the retina caused by diabetes).<sup>203</sup> Ocular examination at Stobhill was unremarkable, however, and she was discharged in to the care of her GP.<sup>204</sup>

**7.112** Later in 1990 Mrs O'Hara became unwell. Her GP arranged liver function tests, which were found to be mildly deranged. The GP told her that there were problems with the results and referred Mrs O'Hara to the GRI for tests on 29 May 1990.<sup>205</sup> In her referral letter, the GP wrote that Mrs O'Hara did not take any alcohol and wondered whether

<sup>204</sup> Letter to GP dated 10 May 1990 [OHA.001.2539]

<sup>205</sup> Letter [OHA.001.1178]

drug therapy was the cause of her abnormal LFTs.<sup>206</sup> Mrs O'Hara continued going to the GP 'for several months'.<sup>207</sup> It seems to be in the context of those visits that consumption of alcohol was raised, presumably because she had persistently abnormal liver blood tests. Mrs O'Hara's daughter, Mrs Roseleen Kennedy, said that her mother had commented that the GP kept asking her whether she was drinking. In fact, she drank very little and became upset that she appeared to be being dealt with as an alcoholic.<sup>208</sup> Given her liver function test results, however, questions about alcohol consumption were routine. As reported in the letter to the GRI, the GP accepted that Mrs O'Hara did not drink alcohol.<sup>209</sup>

**7.113** The GRI's report to her GP on 1 June 1990 stated that Mrs O'Hara's cardiac position was good. No hepatic enlargement was identified on examination in hospital. The GP was, however, encouraged to continue with liver function tests and to seek ultrasound tests or a gastroenterologist's report if her liver function tests continued to show mild derangement.<sup>210</sup>

**7.114** In September 1990, the GP referred Mrs O'Hara to the GRI Gastroenterology Department commenting that she had mild persistent derangement of her LFTs and frequent loose bowel motions. The GP noted that Mrs O'Hara had only ever taken a moderate amount of alcohol and that her liver function tests were still deranged on abstinence.<sup>211</sup> In a full report dated 5 November 1990, the gastroenterology registrar, Dr J Morris, set out the clinical findings on examination that day.<sup>212</sup> Significantly, the tip of the spleen was palpable. Overall, it was thought that she had mild congestive cardiac failure. Dr Morris did not feel that this explained her abnormal blood tests, however.

**7.115** In her history so far Mrs O'Hara had experienced a significant exposure to blood transfusion. Dr Morris did not have that information available when examining her. In his letter to the GP on 5 November 1990, he wrote:

Although I was unsure whether she received blood transfusions with her various operations in the past ... I suppose this remains a possibility and I have therefore checked hepatitis screens including hepatitis C, further I have rechecked liver function tests, urea and electrolytes, chest x-ray, ECG, echocardiogram auto antibodies and an abdominal ultrasound. I think it is important that we check on the function of her valve replacement to [see] whether there is any regurgitation contributing to heart failure. Secondly we have persistent abnormal LFTs and hopefully the above investigations will give some idea of how we should proceed with further investigations. This may well be on the basis of a liver biopsy should the other investigations fail to turn up a clue to the problems.<sup>213</sup>

**7.116** Blood was taken for hepatitis tests on 5 November 1990. Dr Morris wrote to Mrs O'Hara's GP on 4 December, observing that the recent investigations had shown a fair degree of valve dysfunction that would need to be looked at further.<sup>214</sup> By then the results of some tests had been reported by the GRI Microbiology Department. HBsAg tests (for

Hepatitis B) were negative;<sup>215</sup> the IgM anti-HAV (for Hepatitis A) test was negative;<sup>216</sup> Epstein-Barr virus and Cytomegalovirus had not been detected.<sup>217</sup> The test for Hepatitis C antibody was not reported until 18 December 1990: it too was negative.<sup>218</sup> Dr Morris said he would write to Mrs O'Hara with a view to bringing her back to the clinic to discuss the results.

**7.117** Dr Morris duly wrote to Mrs O'Hara on 4 December 1990, enclosing a clinic appointment for two weeks later.<sup>219</sup> He saw her on 17 December. According to a file note prepared in January 1991, Mrs O'Hara remembered a series of tests, including an ECG, being carried out at the 17 December appointment. She was told that she would be referred to Cardiology and that she would receive an appointment in the near future.<sup>220</sup> She was referred to Dr AR Lorimer, a cardiologist at the GRI, by Dr Morris on behalf of Dr JF MacKenzie, the Senior Consultant, on 17 December.<sup>221</sup> In his letter to Dr Lorimer, Dr Morris referred to her raised LFT results and said:

The most striking abnormality, however, on examination was evidence of both mitral and tricuspid regurgitation .... An Ultrasound of the abdomen shows the liver and spleen to be enlarged with splenic vein dilatations. Overall, these are the appearances we would expect with congestion secondary to primary cardiac abnormality. Certainly we feel that this is the most likely cause of her abnormal liver function tests.

**7.118** Mr El Fiky from Cardiothoracic Surgery at the GRI saw Mrs O'Hara on 18 January 1991. His clinical findings supported Dr Morris. An echocardiogram had shown that her heart valves and consequent heart failure were more severe than had been expected and he recommended that she should have an early appointment at Dr Lorimer's clinic with a view to mitral valve replacement as soon as possible.<sup>222</sup> Dr Lorimer saw her and reported to her GP on 7 February.<sup>223</sup> He found signs of a degree of incompetence and stenosis of the valve. He reported that the liver was not unduly enlarged that day. He suspected a further myocardial factor and arranged for her admission for further, more detailed evaluation.

**7.119** She was duly admitted to the GRI on 25 February 1991. She was seen by Mr Dimitri of the department of Cardiac Surgery, where cardiac catheterisation and transoesophageal echocardiogram investigations were carried out to investigate her mitral valve.<sup>224</sup> The discharge notes recorded that Mrs O'Hara had 3cms hepatomegaly (enlargement of the liver) which was slightly tender. LFT results were reported to be normal apart from slightly raised Gamma-glutamyltransferase (GGT, an enzyme found in many body tissues but especially the liver. Elevated GGT can be a marker of liver disease).<sup>225</sup> This minor abnormality was not considered to be significant.

<sup>224</sup> GRI discharge report dated 3 April 1991 [OHA.001.1155]

<sup>225</sup> Ibid [OHA.001.1155] at 1156

**7.120** Mr Dimitri reported to Dr Lorimer on 7 March. Clinically, Mrs O'Hara had signs of prosthetic malfunction and was in atrial fibrillation (deviation from the normal rhythm of the heart) and there was stenosis (narrowing) of the valve. It was noted on examination that her increased hepatomegaly suggested a progressive enlargement of the liver.<sup>226</sup> Mr Dimitri commented that replacement of her mitral prosthesis was required but suggested to Dr Lorimer that an angiogram might be appropriate to delineate her coronary anatomy.

**7.121** Meanwhile, a further appointment had been arranged for Mrs O'Hara to attend the Gastroenterology Clinic at the GRI on 11 March 1991. She did not attend, however. The consultant gastroenterologist, Dr MacKenzie, thought this might be explained by the fact that she had just returned home from her hospital admission (she had been discharged on 1 March) and wrote to her GP that she would be sent another appointment for a month later.<sup>227</sup> Investigations have not shown whether or not Mrs O'Hara or her GP asked for or received a further appointment. There is no evidence in the medical records that she attended Gastroenterology about this time.

**7.122** On 8 April 1991, Professor Lorimer, as he had become, reported to Mrs O'Hara's GP, copied to Mr Dimitri, with the GRI's clinical summary commenting that she was a candidate for mitral valve replacement and confirming that she was on his waiting list for the further investigation proposed by Mr Dimitri.<sup>228</sup> The GP had written to Professor Lorimer on 17 May questioning the need for further coronary angiography<sup>229</sup> but the procedure was carried out in July 1991. Her coronary arteries were normal. It was decided that Mrs O'Hara would go forward to mitral valve replacement and that otherwise her management should continue on current lines.<sup>230</sup> Mr Dimitri confirmed in a letter to Professor Lorimer on 30 July that she would be admitted for replacement of her mitral prosthesis.<sup>231</sup>

**7.123** The mitral valve replacement surgery was delayed for family reasons. Mrs O'Hara was admitted on 15 October 1991. She had a valve replacement with a St Jude bileaflet mechanical valve on 18 October 1991.<sup>232</sup> The procedure was successful.

**7.124** Mrs O'Hara was monitored at the GRI. She was seen at Mr Dimitri's clinic on 17 December 1991 when it was noted that her recovery had been quick and smooth, that she was doing well and had no complaints.<sup>233</sup> She was reviewed in February 1993.<sup>234</sup> There were no symptoms of heart failure and her prosthetic valve was functioning normally. Her next annual review, in February 1994, was unremarkable.<sup>235</sup>

**7.125** Mrs O'Hara was referred to the Diabetic Day Unit at Stobhill in August 1994. On examination there, she was found to have hepatosplenomegaly (enlarged liver and spleen). The consultant physician, Dr McLaren, who was surprised at the finding, thought that it might be secondary to her mitral valve replacement and proposed writing to the cardiac unit at the GRI. If hepatosplenomegaly had been noted before it was unlikely to be

<sup>230</sup> Discharge letter from the GRI to GP dated 5 August 1991 [OHA.001.1151]

<sup>231</sup> Letter [OHA.001.1154]. At this stage it was known that the operation would be delayed until after a family wedding at the beginning of October.

<sup>232</sup> GRI discharge report [OHA.001.2520]

<sup>233</sup> Letter from GRI to GP dated 17 December 1991 [OHA.001.1138]

<sup>234</sup> Letter from GRI to GP dated 16 February 1993 [OHA.001.1137]

<sup>235</sup> Letter from GRI to GP dated 27 February 1994 [OHA.001.1136]

significant. If it was new, however, he thought that an ultrasound examination, at least, would be required.<sup>236</sup> He wrote to that effect on 5 August 1994.<sup>237</sup> He was to find the reply from the cardiothoracic surgeon less than illuminating:

In the absence of gross failure it would be appropriate to investigate the hepatosplenomegaly. I suspect that we will not find anything but nevertheless there is justification for doing so.<sup>238</sup>

**7.126** On 16 August 1994, Dr McLaren wrote to Mrs O'Hara's GP.<sup>239</sup> He said he had received a 'rather delphic communication from the cardiothoracic surgeons, the burden of which ... is that they have not noted hepatosplenomegaly before'. Further investigations were put in hand. Dr McLaren arranged for an ultrasound of her abdomen. On 9 September, Dr McLaren wrote again, confirming that Mrs O'Hara had very marked splenomegaly (enlarged spleen) and mild hepatomegaly. A biochemical screen on her last visit had been normal but he had done a full blood screen and arranged ultrasound examination.<sup>240</sup> On 22 September, Dr McLaren intimated the results of tests.<sup>241</sup> Ultrasound tests had confirmed the presence of splenomegaly and suggested a degree of portal hypertension (high blood pressure in the portal vein system at the liver). He suggested, correctly, as events were to prove, that the findings might all be secondary to cirrhosis.

**7.127** Dr McLaren saw Mrs O'Hara again on 19 October 1994. Mrs O'Hara told him that she had previously been told there was 'something wrong with her liver' due to her heart disease. Dr McLaren's report to the GP reflected some annoyance. Hepatosplenomegaly had been noted in 1990 and he asked for correspondence from the GP's records which might relate to the topic. Further ultrasound examination had confirmed the presence of hepatomegaly and there was further indication of cirrhosis.<sup>242</sup> The GP responded on 4 November 1994, enclosing the GRI report of 3 April 1991 and confirming that Mrs O'Hara had deranged LFTs in January 1994.<sup>243</sup>

**7.128** Following discussions between Dr McLaren and Dr Dunn, Mrs O'Hara was seen in the department of cardiology, Stobhill, on 21 December 1994 by Dr Dunn and Dr Tait, the registrar in cardiology. The registrar subsequently reported to Dr McLaren and to the GP.<sup>244</sup> The letter noted that Dr McLaren had detected hepatosplenomegaly and that possible fat infiltration of the liver had been detected with prominence of the portal vein and marked splenomegaly. Dr Mutimer thought, in retrospect, that any fat infiltration was probably related to Mrs O'Hara's diabetes.<sup>245</sup> The letter also acknowledged that abnormalities in liver function tests had been detected in 1990, with hepatomegaly and with the tip of the spleen possibly being palpable. It was noted that the slight enlargement of the liver and spleen found in 1990 were attributed to right heart failure consequent to mitral re-stenosis with a degree of pulmonary hypertension. The liver abnormalities did not appear to have been re-checked following her mitral valve replacement in 1991.<sup>246</sup> Her condition

<sup>242</sup> Letter to GP dated 26 October 1994 [OHA.001.2494]

<sup>243</sup> Letter [OHA.001.2493]; GRI discharge report dated 3 April 1991 [OHA.001.1155]

<sup>244</sup> Letter from Stobhill dated 5 January 1995 [OHA.001.2486]

<sup>245</sup> Dr Mutimer – Day 3, page 42

<sup>246</sup> The implication of the comment appears to be that if right heart failure had been the cause of the enlarged liver and spleen in 1990, the abnormalities would have disappeared following the successful operation.

on clinical examination was reported. The conclusion reached was that an alternative cause for her hepatosplenomegaly appeared to be indicated and required investigation.<sup>247</sup> Dr Dunn explained that, because of the success of the mitral valve procedure and her satisfactory cardiac status at the time, it was unlikely that the condition of her liver and spleen was related solely to her heart disease.<sup>248</sup>

**7.129** Investigation of Mrs O'Hara's liver was initiated by Dr Tait.<sup>249</sup> Dr Dunn explained that, at that time, doctors in his department were often 'gatekeepers,' doing initial investigations before referring on for other specialist consideration.<sup>250</sup> Hepatitis testing was carried out and reported in February 1995. It was confirmed that Mrs O'Hara was positive for Hepatitis C antibody.<sup>251</sup> Dr Mutimer explained that this test confirmed that she had been exposed to Hepatitis C at some stage but not whether the virus was still present.<sup>252</sup> Later tests confirmed that it was.<sup>253</sup>

**7.130** Mrs O'Hara was reviewed at Stobhill cardiology clinic on 27 February 1995.<sup>254</sup> She had developed herpes zoster (shingles) affecting her leg and abdominal wall. Typically, the condition causes pain and, in Mrs O'Hara's case, irritation of the nerves continuing after her rash had resolved. She had been admitted to hospital as an emergency as a result of this complication, known as post-herpetic neuralgia.<sup>255</sup> Further investigation of her hepatosplenomegaly was delayed until she was feeling better.<sup>256</sup> However, investigation continued and Dr Dunn reported to her GP on 29 March 1995.<sup>257</sup> Mrs O'Hara's case had been discussed with gastroenterology colleagues and it was agreed that liver biopsy was indicated. Advice was given on her continuing cardiac issues. Dr McLaren wrote to the GP on 3 April.<sup>258</sup> He reported on her herpes zoster infection. In addition he commented on the possibility that the antibodies against Hepatitis C (indicating Hepatitis C infection) that had been identified were attributable to blood transfusions and suggested that would explain why she might have developed cirrhosis, the presumed diagnosis. Fuller, subsequent, evaluation was to prove that he was probably right.<sup>259</sup>

**7.131** On 12 May 1995 Dr Dunn reported to the GP on the results of CT scanning of Mrs O'Hara's abdomen.<sup>260</sup> There was significant hepatosplenomegaly and, in particular, splenomegaly. It was suggested that the condition of her lymph nodes might have a malignant source, for example lymphoma.<sup>261</sup> This was to prove a false trail.

**7.132** Bone marrow and liver biopsy investigations were carried out in June and July 1995.<sup>262</sup> The tests were related to the risk of a malignant source of her lymph node condition.<sup>263</sup> There was no evidence of lymphoma or of malignancy.<sup>264</sup> There was no

evidence of malignant infiltration of the bone marrow. The strong likelihood was that the 'enlarged lymph nodes' that had prompted discussion of lymphoma were in reality enlarged blood vessels in the abdomen resulting from portal hypertension (as had been suggested in September 1994). Liver biopsy showed cirrhosis with lymphocytic infiltrate, appearances that were typical of Hepatitis C.<sup>265</sup> The lymphocytic infiltrate was an indication of the body's immune cells reacting to the presence of the virus in the liver.<sup>266</sup> Mrs O'Hara was told that she had cirrhosis.<sup>267</sup>

### **Mrs O'Hara's medical history after July 1995**

**7.133** Until about mid-1995, Mrs O'Hara's liver disease was relatively asymptomatic. She appeared to her daughter to have been well until June of that year. She looked after her granddaughter, born in 1992, from the point when Mrs Kennedy returned to work, until June 1995. At that point, Mrs O'Hara began to appear unwell and complained of fluid retention in her legs and of a swollen abdomen. She looked pale and tired, felt nauseated and started to lose her appetite.<sup>268</sup> Mrs Kennedy said that her mother slowly deteriorated from 1995.<sup>269</sup> The family account of Mrs O'Hara's general health was a reasonable fit with her medical history. In the period 1991–94, as noted later, she frequently attended her GP for relatively minor ailments. Late 1995 was the time when Mrs O'Hara began undergoing extensive and continuing investigations.

**7.134** After July 1995, when the diagnosis of cirrhosis was finally arrived at and intimated to Mrs O'Hara, matters did not progress swiftly for a time. Mrs O'Hara continued to attend her GP with relatively minor complaints.<sup>270</sup> She was examined following spontaneous haemorrhage in her left eye on 29 July. On 3 August, she reported pain in her left shoulder. Co-codamol was prescribed but did not help. Pain in the back of her neck was extending to her hand. Her shoulders were stiff and she had chest pain. She also reported vomiting and sweating.<sup>271</sup> After review of the findings in September 1995, Dr Prasad, a Stobhill cardiologist, indicated to the GP that Mrs O'Hara should be reviewed by Dr Forrest, consultant gastroenterologist at Stobhill.<sup>272</sup> A letter of referral was sent to Dr Forrest on 12 September 1995.<sup>273</sup> Enclosed with the letter was a copy of Mrs O'Hara's 'recent clinic letter', which appears to have been Dr Prasad's letter to the GP. It stated:

This lady who was sent to our clinic with possible congestive cardiac failure was found to have hepatosplenomegaly and subsequently has been investigated by the haematologists and ourselves. The liver biopsy showed cirrhosis with lymphatic infiltrate. The appearances were non-specific but in keeping with Hepatitis C .... In view of these findings I think in the first instance we should ask our Gastroenterology colleagues to review her and further assess the need for additional treatments such as Interferon .... I will arrange to see her again in four months time but we will wait until Dr Forrest's review.<sup>274</sup>

<sup>273</sup> Letter from Dr Prasad to Dr Forrest both Stobhill dated 12 September 1995 [OHA.001.1011]. (This letter was dictated 11 September but typed and presumably sent on 12 September 1995 rather than on 12 May 1995 which appears to be a typographical error).

<sup>274</sup> Letter from Stobhill to GP dated 12 September 1995 [OHA.001.2468]

**7.135** In 1995 Stobhill Hospital was managed, and its consultants were employed, by Stobhill National Health Service Trust. Responsibility for the hospital and its staff now lies with Greater Glasgow Health Board.

**7.136** Dr Forrest replied on 3 November 1995, without seeing Mrs O'Hara. Since this represented a significant stage in her care it is appropriate to quote from his letter:

I note that she was found to have hepatosplenomegaly around 1990 and that a recent liver biopsy shows an established cirrhosis. This could be idiopathic [of unknown origin] but could be related to Hepatitis C, but there is no obvious continuing Hepatitis from the biopsy report.

If her cirrhosis is due to Hepatitis C (and of course it could be cryptogenic [another term indicating unknown origin]) then she must have contracted her Hepatitis C very many years ago as cirrhosis develops very slowly following infection with Hepatitis C.

Interferon has been used for Hepatitis C but the results in terms of clearing the virus from the patient's serum are disappointing. Perhaps only around 25% of patients will respond on a long term basis and all the evidence suggests that patients who are cirrhotic have a much lower response rate than this. The other factor is that Greater Glasgow Health Board has instructed the General Practitioners not to prescribe Interferon for chronic Hepatitis C and the Trust will also not prescribe it. The Health Board have apparently given £200,000 for a trial to be started at the Royal and the Western. At the present time I have not seen the protocol to see which sort of patients would be suitable for treatment, but I doubt if this lady would be a candidate. Having said that I will arrange to review her liver biopsy to see if there is any ongoing evidence of Hepatitis and will write to you further after that.<sup>275</sup>

**7.137** On 30 November 1995, Mrs O'Hara was seen at Dr Dunn's clinic.<sup>276</sup> The cardiac findings, in context, suggested that her cardiac status overall was stable.<sup>277</sup> Dr Dunn explained that his department remained reasonably happy with Mrs O'Hara's heart condition at this time and this remained the case up to about 1998.<sup>278</sup>

**7.138** Dr Bong (Senior House Officer, Department of Cardiology, Stobhill) renewed the request to Dr Forrest for advice in March 1996.<sup>279</sup> Dr McLaren reminded Dr Forrest of the request in May.<sup>280</sup> By letter from a senior registrar in Cardiology, which was dictated on 28 June and typed on 12 July, Mrs O'Hara's GP was told that Dr Forrest planned to review her case on the day of dictation and that the GP would hear directly from Dr Forrest.<sup>281</sup>

**7.139** Dr Forrest reviewed Mrs O'Hara's liver biopsy but did not see her in person. He wrote to Dr McLaren on 10 July 1996 apologising for his delay in responding. He confirmed that her liver biopsy in 1995 showed established cirrhosis and that he had reviewed the biopsy recently.<sup>282</sup> He thought that she did not need a repeat liver biopsy. He doubted very much whether she was a candidate for Interferon treatment. Dr McLaren wrote directly to Mrs

<sup>282</sup> Letter from Dr Forrest to Dr McLaren, both Stobhill [OHA.001.1017]

O'Hara and to the GP passing on the information from Dr Forrest that repeat liver biopsy was not necessary.<sup>283</sup> These matters are discussed more fully in paragraphs 7.202–7.211 below.

**7.140** Mrs O'Hara was seen at Stobhill Department of Haematology on 21 April 1997.<sup>284</sup> She had been referred because of her neutropenia and thrombocytopenia (reductions in white cell and platelet counts in the blood respectively), both of which are observed in patients with cirrhosis.<sup>285</sup> She had hepatosplenomegaly and was anaemic.<sup>286</sup> The haematologist found that Mrs O'Hara was developing early iron deficiency. He arranged for further endoscopic examination to see whether she was bleeding from her upper gastrointestinal tract as a consequence of her cirrhosis. Subsequent endoscopic examination on 14 July 1997 showed that there were varices proximal to the gastro-oesophageal junction.<sup>287</sup> There was evidence of portal hypertension with the varices but it was thought that this was extremely unlikely to be the cause of her iron deficiency anaemia. There were no stigmata (signs) of recent bleeding. A report was sent to Mrs O'Hara's GP on 28 July.<sup>288</sup>

**7.141** Dr Mutimer interpreted the report:

They would be looking for a cause of blood loss ... [T]he haematologist thinks that the patient is iron-deficient, which means there is likely to be some chronic blood loss. That can be due to the portal hypertension, it can be due to the cirrhosis. It is appropriate that she has an endoscopy for two reasons. One is to see whether the varices are present and if they are small or large, and at the same time the endoscopist can look around the stomach to make sure that there is no additional cause of blood loss, like a stomach ulcer or a stomach cancer.<sup>289</sup>

**7.142** Mrs O'Hara was admitted to Stobhill as an emergency patient between 21 and 27 May 1999 for 'stabilisation of really quite severe cardiac failure'.<sup>290</sup> Dr Dunn explained that valve prostheses last a variable period of time. It appeared that some elevation of pressure was starting on the right side of the heart, leading to swelling of the ankles. Sometimes this could be reactive: it did not necessarily mean that the valve was the source of the trouble as patients often had a degree of elevation of the pressure on the right side of the heart at the time of the operation. This can be relieved but can subsequently return and the tricuspid valve (located on the right side of the heart) can start to dilate creating back pressure causing failure, predominantly of the right side of the heart. Ankle swelling may also occur as a consequence of cirrhosis and portal hypertension. From Dr Dunn's recollection, her problems were with the right side rather than the left side of the heart.<sup>291</sup>

**7.143** In September 2001, Mrs O'Hara was again reviewed.<sup>292</sup> Her shortness of breath was stable but she reported chest pain on exertion. It was thought that the pain was likely to be ischaemic in nature (caused by inadequate flow of blood to the heart). In Mrs O'Hara's case this was probably caused by her atrial fibrillation, a heart rhythm disorder.<sup>293</sup>

<sup>293</sup> Dr Dunn – Day 3, pages 125–126

**7.144** In March 2002, Mrs O'Hara reported that medication had reduced her chest pain and, on examination, she appeared well.<sup>294</sup> Her medication remained as before. However, to achieve stability of her heart complaint, she required a significant dose of Frusemide, a diuretic.<sup>295</sup> By this time her diabetes had already become severe enough to require regular insulin treatment.<sup>296</sup>

**7.145** Mrs O'Hara became very unwell in March 2003. She had abdominal pain and was vomiting.<sup>297</sup> Her GP at Springburn Health Centre thought she had pancreatitis. He referred Mrs O'Hara to Stobhill on 24 March 2003.<sup>298</sup> She had developed right hypochondrial (under the ribs) pain. The GP suggested urgent abdominal ultrasound examination. Her liver function tests were mildly abnormal but within her usual range.<sup>299</sup> A Hepatitis C PCR<sup>300</sup> test in April 2003 was positive, showing that the Hepatitis C virus was still present at that time.<sup>301</sup> A CT scan on 31 March showed pronounced hepatosplenomegaly. In addition, there were extensive varices, some of which were entwined round the pancreas explaining the previous belief, arising from the earlier ultrasound examination, that there might have been a pancreatic mass. There was no such mass. There was moderate ascites (accumulated fluid in the abdomen).<sup>302</sup> She had an enlarged heart. There were gallstones. The cause of her pain was severe pancreatitis.<sup>303</sup> The investigations did not disclose another cause of her pain.<sup>304</sup> In a patient of Mrs O'Hara's age, the most common cause of pancreatitis is probably gallstones and, in severe cases, it is frequent practice to try to clear stones away from the bile duct.<sup>305</sup>

**7.146** Mr Robertson took up Mrs O'Hara's care at Stobhill. His initial likely diagnosis was gallstone acute pancreatitis.<sup>306</sup> Her amylase count was many times over the reference level applied at Stobhill to confirm a diagnosis of acute pancreatitis in association with her other symptoms and, in particular, gallstones.<sup>307</sup> She had raised INR (International Normalised Ratio: an indication of how easily the blood clots, normally measured for patients treated with warfarin).<sup>308</sup> After a period of conservative management that appeared to stabilise her condition, CT examination of her abdomen showed marked changes of acute pancreatitis but no obvious necrosis (death of cells or tissue) or local complication. Of the alternative approaches to open surgery, laparoscopic cholecystectomy (removal of gall bladder) was excluded by anaesthetic considerations, including the difficulty in restoring natural respiration after surgery under artificial ventilation.<sup>309</sup> It was therefore decided to proceed to ERCP and endoscopic sphincterotomy, procedures that could be performed under sedation.<sup>310</sup>

**7.147** The surgical procedure, as described in evidence by Mr Robertson, to deal with Mrs O'Hara's gallstones was protracted and difficult.<sup>311</sup> The target area was very small and the surrounding mucosa (mucous membrane) swollen.<sup>312</sup> An initial procedure failed.<sup>313</sup> A second procedure was partly successful in that the sphincter muscle, the ampulla of Vater, was cut. Difficulties had been anticipated on account of Mrs O'Hara's other health problems and there was a risk of bleeding. The cut caused bleeding that had to be dealt with and the procedure was suspended with only partial success having been achieved.<sup>314</sup> A third attempt on 18 April completed the operation.<sup>315</sup> The bile duct was cleared of the obstructions (stones) that had gathered at its junction with the pancreas.<sup>316</sup>

**7.148** Mr Robertson asked for cardiological and gastroenterological input to help her overall management. It was known that Mrs O'Hara had underlying liver pathology: she had cirrhosis. It was also known that she had cardiac disease and impaired heart function as a result. The control of these conditions by medication was impaired and the symptoms that they might cause were more manifest.<sup>317</sup> Furthermore she had insulin-dependent diabetes.

**7.149** Her pancreatitis seemed to be resolving. However, she developed a tense abdomen with marked ascites, probably reflecting a combination of decompensated<sup>318</sup> hepatic and cardiac failure, along with a degree of hypoalbumina (shortage of white blood cells), and cellulitis (bacterial infection of the skin) affecting mainly the lower limbs. The medication that had controlled her liver and heart disease lost effectiveness. With gastroenterological and cardiac help, she seemed to improve but there was marked oedema below the knees.<sup>319</sup> Mr Robertson thought that bacterial endocarditis (inflammation of the lining of the heart cavity) could have developed, but accepted the view of Dr Petrie that that was unlikely.<sup>320</sup>

**7.150** On 3 May, Mrs O'Hara deteriorated further, with increasing confusion and shortness of breath. She was clearly moving in the direction of 'multi-organ failure', a condition that is associated with very high mortality. Consideration had been given to ventilation in the Intensive Therapy Unit but it was felt that she could not be removed from artificial ventilation once it had been commenced. Hence she was moved from the surgical unit and admitted to the coronary care unit for intensive cardiac monitoring and support.<sup>321</sup>

### **Mrs O'Hara's final admission and death**

**7.151** Mrs O'Hara died on 7 May 2003. Her final admission was very difficult and complicated. She had pancreatitis. Gallstones were probably the most common cause of pancreatitis in a patient of her age and it was common practice to try to clear some of these away from the bile duct. She developed cellulitis. In the course of this illness Mrs O'Hara had a lot of problems with fluid retention and that would be manifest in a couple of ways. One would be that she would develop ascites, which was seen on the

CT scan, but, in addition to that, the fluid retention was likely to be more generalised and particularly to affect her lower limbs and buttocks. In those circumstances there was a susceptibility to infection because of swelling of the tissue with fluid. In the event, she developed very serious infection in those tissues.<sup>322</sup>

**7.152** As noted in paragraph 7.103, the causes of death registered on her death certificate were hepatic failure, septic shock and mitral valve disease.<sup>323</sup> Mrs Kennedy had commented on the absence of reference to Hepatitis C.<sup>324</sup> When asked if he would have expected Hepatitis C to have been mentioned, Dr Mutimer said:<sup>325</sup>

Yes, it is a cause of the liver disease, so if the liver failed, then it would be appropriate that Hepatitis C is listed on the death certificate.

**7.153** He was asked if, by 'appropriate' he meant that it should have been listed and he confirmed that he did.<sup>326</sup> In relation to pancreatitis, he added:

I think that pancreatitis seems to be missing as well ... her final illness was due to severe pancreatitis. At the end of that illness ... the cause of death was infection. That would be very typical of severe pancreatitis. The ability to cope with an illness of this severity would be affected by the fact that the patient has cirrhosis, and the cause of the cirrhosis is Hepatitis C. So the liver was not the cause of the final illness but it probably affected her potential to survive this illness, but I can't say to what extent because patients with normal livers die of severe pancreatitis in this sort of setting.<sup>327</sup>

**7.154** Dr Mutimer explained his view that Hepatitis C infection was unlikely to have made a major contribution to shortening Mrs O'Hara's life. He said:

[I]t was certainly my view after going through all of the records ... I can only have an impression. I never saw the patient, of course, but it was my impression that her health was not very good at that stage [between 1999 and 2003] and that there was diabetes, there was possibly additional cardiac problems, possibly angina. So it is difficult in that setting to say what her prognosis would be if she did not have cirrhosis of the liver.

On balance, I think that her life expectancy was not long because of those issues. The Hepatitis C and the cirrhosis may have shortened her life.<sup>328</sup>

**7.155** Asked to explain what he meant by 'may have shortened her life', he said:

I think "may" means a better than 50 per cent chance that it contributed but ... severe pancreatitis in a patient aged 72 is associated with ... severe morbidity and with mortality, and that can be observed regardless of the presence or absence of cirrhosis. I think that the cirrhosis may have contributed to the fact that this patient did not survive the illness.<sup>329</sup>

<sup>328</sup> Ibid pages 83–84

<sup>329</sup> Ibid page 80

**7.156** In the days leading to her death, many tests were carried out. Dr Mutimer commented on some of the results relating to her liver.<sup>330</sup> Having looked at the records of her prothrombin time (a measure of coagulation activity) measured by INR, Dr Mutimer confirmed his view that Mrs O'Hara's liver managed remarkably well in the early phases of this final admission, despite her severe pancreatitis.<sup>331</sup> In a patient with cirrhosis of the liver who developed a serious problem elsewhere, like pancreatitis or any other serious non-liver illness, then probably the best way to see whether the liver had sufficient strength to cope with the stress was to look at the patient's serum bilirubin<sup>332</sup> level and also the INR. It was really only at the very end of Mrs O'Hara's life that the bilirubin started to go up. Her INR was affected by warfarin. The doctors had to stop the warfarin but, when they did that, Mrs O'Hara's prothrombin time returned almost to normal values. The liver is responsible for the synthesis of several proteins required for normal blood clotting. If the function of the liver is impaired, that is reflected in prolonged INR. Normal INR implies that the liver is functioning well. Mrs O'Hara's liver was coping remarkably well during the first weeks of this really very serious illness after withdrawal of warfarin therapy. This indicated to Dr Mutimer that if she had not developed serious illness, the liver would still have had 'significant mileage' left in it.<sup>333</sup>

**7.157** Dr Mutimer noted that, in the last few days of her illness, her C-reactive protein was very high, as was her white cell count. These were markers of very severe infection.<sup>334</sup> Her albumin count was indicative of severe pancreatitis.<sup>335</sup> She had renal failure and worsening hepatic failure in the context of overwhelming sepsis (infection).

**7.158** Dr Mutimer's view of the cause of death was sepsis, due to pancreatitis, with contributory causes including cirrhosis due to Hepatitis C and diabetes.<sup>336</sup> Mr Robertson thought one could not express a view on her prospects if cirrhosis and Hepatitis C were removed from the equation: her morbidities were all interrelated.<sup>337</sup>

**7.159** In his report for the Inquiry, Dr Petrie expressed the view that Mrs O'Hara had 'overwhelming sepsis, felt likely secondary to pancreatic collection. She tolerated this poorly due to her longstanding liver and heart disease and developed new acute renal failure'.<sup>338</sup> Dr Dunn commented:

Yes, I think that's fairly accurate. Often in these situations – I mean, acute pancreatitis is in itself a very severe illness and when the patient is afflicted with that and already has significant multi-organ difficulties, and in her case I think her diabetes and her extensive past cardiac conditions were put under the kind of stress with the pancreatitis, that while she was managing not too badly, the pancreatitis just led to a failure of these other organs. I think it is just an effect almost like a domino effect. If one system goes, then the next system goes under pressure and so on and so forth. So I would think that certainly the sepsis was the – the result of the pancreatitis was what caused this. So I would agree with

that. I get the impression that on reflection, Dr Petrie felt that Hepatitis C should have been mentioned in the death certificate and I would agree with that.<sup>339</sup>

**7.160** Dr Dunn, having re-considered Mrs O'Hara's history of diabetes, her cardiac status and Hepatitis C, said:<sup>340</sup>

I have looked at this again, just reflecting on it, and I think there is no doubt these factors, each of them would contribute a substantial increase, perhaps doubling. If we say that mortality from the pancreatitis was, say, 7 to 10 per cent, I think each of these factors would add another 10 per cent, perhaps not the diabetes but her cardiac status and her Hepatitis would each, in my view, contribute another 10 per cent to decreasing her likelihood of survival.

So whereas it would have been say 10 per cent, it might have gone to 20 per cent because of the presence of Hepatitis C and because of her cardiac failure, but that's not an exact science. I have discussed this with experts on pancreatitis and that was their kind of sense from hearing the situation, that that would be the kind of impact of these additional conditions on her survival.

**7.161** However, he was not wholly comfortable with arithmetical or mathematical expressions in this context: it was more a multi-system failure and the accumulation of problems significantly increased the mortality risk. It was, he thought, more a matter of sense rather than modelling.<sup>341</sup> In a patient over 70 years of age, severe acute pancreatitis, quite apart from the patient's other diseases, carries a high mortality.

**7.162** Dr Dunn discussed the possible connection between Mrs O'Hara's cardiac condition and the development of cirrhosis in view of the known connection in certain circumstances.<sup>342</sup> Cardiac cirrhosis rarely causes the classic cirrhotic pattern seen in primary liver disease. Mrs O'Hara's history was not consistent with such a connection. Dr Dunn's view was that her cardiac condition did not pre-dispose her in any significant way to the development of cirrhosis, though he did not exclude it entirely.<sup>343</sup>

## Cause and date of Hepatitis C infection

### *The Hepatitis C antibody test of 5 November 1990*

**7.163** As noted in paragraph 7.116, tests for antibody to Hepatitis C were carried out on blood samples taken on 5 November 1990. The samples were reported to be negative after microbiological testing. If that was a true reflection of Mrs O'Hara's condition – a truly negative test – it is highly unlikely that she acquired Hepatitis C virus infection prior to November 1990.

**7.164** In retrospect, however, having regard to the progression of Mrs O'Hara's Hepatitis C-related liver disease, it is now clear that the negative test result was a false negative. In Dr Mutimer's view that was almost certainly the case: Hepatitis C infection was established and had already caused cirrhosis at this stage.<sup>344</sup> As a matter of probability there is no reason to doubt that the result was a false negative.

---

<sup>339</sup> Day 3, pages 129–130

<sup>340</sup> Ibid pages 132–133

<sup>341</sup> Dr Dunn – Day 3, page 134

<sup>343</sup> Ibid pages 131–132

<sup>344</sup> Ibid pages 32 and 81; Dr Mutimer's report [BLA.001.2298] at 2301

**7.165** The reliability of the test was explored with Dr Sheila Cameron of the West of Scotland Specialist Virology Centre, one of those who carried out the test (and signed the report of the results on 18 December 1990).<sup>345</sup> In her written statement, she commented that the test would have been carried out using the Ortho first-generation ELISA:

This was the first HCV antibody test. It was introduced in 1989 and was of limited sensitivity and specificity, ie there were false positives and false negatives. No confirmation test was available in our laboratory at that time. I would not exclude HCV infection on the basis of this result. There is a wealth of published data which supports this view.<sup>346</sup>

**7.166** The weight of evidence before the Inquiry indicated that there were problems with the sensitivity of this test. The test results were frequently wrong in Scotland: early work carried out in Glasgow on anti-Hepatitis C virus testing by Dr Dow and others showed a significant proportion of false negative results. A likely explanation is that the tests were developed and validated using North American blood and that the predominant strain (genotype) of the Hepatitis C virus in North America was different from the predominant genotypes in Scotland.<sup>347</sup> So far as appears from the information available to the Inquiry, Mrs O'Hara's Hepatitis C was never genotyped.<sup>348</sup> It is possible, but highly speculative, that this explains the negative result in November 1990. Whatever the explanation, however, it is appropriate to dismiss the test result as a factor bearing on the date of infection.

#### *The cause of Mrs O'Hara's Hepatitis C infection*

**7.167** Having regard to the finding that the November 1990 result was a false negative, and bearing in mind Dr Mutimer's view that on clinical grounds Hepatitis C infection was already established by then, Mrs O'Hara was clearly infected with Hepatitis C some time before November 1990 and the cause of her infection has to be found before that date.

**7.168** Specific blood tests for the presence of Hepatitis C infection were not available anywhere in June 1985, the date of her last transfusion prior to November 1990, and reliable screening tests would not become available in Scotland for some time thereafter. This was because the virus itself was not identified until 1988. Screening for Hepatitis C of blood intended for transfusion commenced in the UK in September 1991. Mrs O'Hara had therefore probably been exposed to unscreened blood on transfusion on four occasions by the date of the false negative test in November 1990.

**7.169** There were two possibilities: blood transfusion or a nosocomial (hospital acquired) source not directly related to transfusion. Dr Mutimer explained:

[I]nfections can be acquired in hospital, it is not just from blood transfusion, and that includes Hepatitis C. So we see people who have acquired Hepatitis C without ever having received a transfusion but who have had complex and difficult medical problems over a long period of time. With them it is likely that they somehow come into contact with it in the hospital setting. So 'nosocomial' refers to that.

---

<sup>345</sup> Test results [OHA.001.1272]

<sup>346</sup> Enzyme-linked Immunosorbent assay; letter from Dr Cameron dated 03 December 2010 [PEN.001.0025]

<sup>347</sup> A brief explanation is given by Dr Dow – Day 4 pages 58–59. The topic is discussed in detail in his report [PEN.001.0016] and in the report of Mr Laing's death. See also: Chapter 16, *Knowledge of Viral Hepatitis 3 – 1986 Onwards*, paragraphs 16.31 and 16.47.

<sup>348</sup> Explained by Counsel to the Inquiry Day 3, page 33.

So the blood may have been the source of Hepatitis C infection, we can't be certain. It is most likely but, with so many and such complex past illnesses, the hospital setting, including the blood transfusion, is likely to have been the source of her infection.<sup>349</sup>

**7.170** So far as nosocomial infection is concerned, Mrs O'Hara had been an orderly in Stobhill Hospital<sup>350</sup> and could have been infected in the course of her work there. She had also been exposed to a large number of procedures in hospital and Dr Mutimer thought that blood transfusion was a more likely cause of infection than some other mechanism. Of Mrs O'Hara's various transfusions, Dr Mutimer said:

[W]e don't know if she had a transfusion in 1963, and in 1963 the frequency of Hepatitis C in the blood donor pool was probably incredibly low, so I don't think it would have been 1963. We know that in [1985] she already had abnormal liver function tests and I suspect it was Hepatitis C. So perhaps the transfusions in 1985 and 1991 are unlikely, in that Hepatitis C was probably already present. Which means 72 and 79, and perhaps the risk then was proportional to the magnitude of the transfusion. So there was one unit in 1972 and two units in 1979. So perhaps Sherlock Holmes might decide on 1979.<sup>351</sup>

**7.171** He thought that it was never going to be possible to know. Dr Dunn thought that the transfusions in 1972, 1979 and 1985 were possibilities<sup>352</sup> but Dr Mutimer's analysis was, on balance, more persuasive.

**7.172** There is no acceptable evidence to suggest that she might have acquired the infection in any other way: nosocomial transmission remains as a possibility but is unsupported by any relevant facts. The probability is that Mrs O'Hara was infected by blood transfusion. Having regard to the volume of transfused blood, the transfusion in 1979 was the more likely of the two earlier events to have infected her.

### **Mrs O'Hara's management as a patient in 1990–91**

#### *The role of Gastroenterology*

**7.173** The final submissions on behalf of the patient interest core participants, including Mrs Kennedy, relative to Mrs O'Hara's management as a patient,<sup>353</sup> raise two questions that relate to this period:

- Whether, following the negative Hepatitis C result in 1990, and against the background of findings of abnormal LFTs, Mrs O'Hara's liver condition should have continued to be monitored by Gastroenterology.
- More specifically, whether consideration should have been given to further investigation once the second generation of HCV tests had become available in September 1991.

**7.174** Expressed in this way, the questions are not very helpful. Together, they imply that Gastroenterology did not continue to monitor Mrs O'Hara after November 1990. As a specific issue, the second has no time reference and no reference to any context defined by Mrs O'Hara's medical treatment.

---

<sup>349</sup> Day 3, page 81

<sup>350</sup> Mrs Kennedy – Day 3, page 3

<sup>351</sup> Day 3, pages 82–83

<sup>352</sup> Ibid page 113

<sup>353</sup> Closing submissions of patient interest core participants (para 5) [PEN.019.0779] at 0781

**7.175** As the narrative at paragraphs 7.114–7.116 above shows, Dr Morris of the Gastroenterology Department at the GRI did continue to deal with Mrs O'Hara's management after November 1990. It appears to be clear that Dr Morris considered that Mrs O'Hara should be seen after that date. In November 1990 he arranged for tests to be carried out, with a view to bringing her back to the clinic to discuss the results. She attended his clinic on 17 December. An arrangement was made at or after that date for an appointment at the gastroenterology clinic on 11 March 1991. Mrs O'Hara did not attend. Mrs O'Hara's failure to attend the clinic is, as Dr MacKenzie suggested,<sup>354</sup> understandable given the intensive care she had been receiving and was continuing to receive at the GRI for her cardiac problems at the time. There is no criticism of Mrs O'Hara. From the medical records it is not possible to form a view of what happened after 11 March 1991 so far as further Gastroenterology clinic appointments are concerned. It is clear, however, that, notwithstanding the referral to the GRI Cardiology Department, the 1990 test results (including the Hepatitis C result reported on 18 December 1990) did not end the GRI Gastroenterology department's interest in Mrs O'Hara as a patient.

**7.176** There is no basis in the written records for a view that the Hepatitis C test result was treated as definitive or that it was the sole or main basis on which diagnosis was reached by Dr Morris and Dr MacKenzie resulting in the referral to the GRI Cardiology. Dr Morris' view, in his report dated 5 November 1990, was that mild congestive cardiac failure did not explain Mrs O'Hara's splenomegaly and abnormal blood tests.<sup>355</sup> He instructed further tests against that background. The particular test finding that Mrs O'Hara was negative for Hepatitis C antibody had not been reported by 17 December 1990, the date of Dr Morris' referral letter to Dr Lorimer, in which he set out the reasons for considering that cardiac investigations were appropriate (particularly the echocardiogram which suggested worsening heart valve problems).<sup>356</sup>

**7.177** Dr Mutimer agreed with Dr Morris' view that chronic mild congestive heart failure might not explain Mrs O'Hara's abnormal liver function tests. He gave additional explanations of his view. Her abnormal LFTs had been causing concern for several months, reflected in questioning about alcohol consumption. In addition, some of the clinical findings suggested significant liver damage: the tip of the spleen was palpable, a potentially significant abnormality which often implies the presence of cirrhosis.<sup>357</sup>

**7.178** Having reviewed the records as a whole, Dr Mutimer's view was that, with the exception of the November 1990 blood test result, everything pointed to Hepatitis C infection.<sup>358</sup> However, he contrasted the state of knowledge of Hepatitis C in the early 1990s with current knowledge. At that time, most GPs and hospital clinicians would have had very little knowledge of Hepatitis C. He said:

I think people's familiarity with Hepatitis C in the early 90s was really quite poor. Remember, the virus was only discovered in 89. The first tests available in clinics in 1990. So a lot of our knowledge about Hepatitis C at that stage was fairly superficial .... Perhaps it is that first test in 1990 which has really thrown them off track, I think, and that was unfortunate because, you know,

---

<sup>354</sup> See paragraph 7.110

<sup>355</sup> Letter to GP [OHA.001.1173]

<sup>356</sup> Dr Morris' referral letter [OHA.001.1168]

<sup>357</sup> Day 3, pages 30–31

<sup>358</sup> Ibid pages 32–33; Report [BLA.001.2298] at 2301

it was a very clever thing for the doctor to do in 1990, to say there has been transfusion. There is liver disease, is it Hepatitis C? And then unfortunately an erroneous result has thrown him off track, I think.<sup>359</sup>

**7.179** It is possible that Dr MacKenzie and Dr Morris were thrown off the track, to some extent, by the negative test result. It is, however, reasonably clear that it was not the test result that interrupted their management of Mrs O'Hara's case. Dr Morris did not express a view that the result was reliable. There were unanswered questions, so far as he was concerned, in his approach to Mrs O'Hara's signs and symptoms. It cannot be said that he treated the result as definitive, given the investigations he instructed into the other signs and symptoms Mrs O'Hara had at the time.

**7.180** In Dr Morris' letter to Dr Lorimer dated 17 December 1990, written on behalf of Dr MacKenzie, he referred to the echocardiogram showing 'moderate to severe mitral regurgitation and mild to moderate tricuspid regurgitation'.<sup>360</sup> It appears that the echocardiogram findings were a significant factor in the gastroenterologists' thinking at the time. Together with enlargement of the liver and spleen, and splenic vein dilatation, these appearances suggested to them that congestion secondary to primary cardiac abnormality was the most likely cause of Mrs O'Hara's abnormal liver function tests. That appears to have been a clinical judgement on the basis of the findings set out in his letter.

**7.181** Mrs O'Hara was to turn out to have severe cardiac problems requiring attention. The decision to refer her to Dr Lorimer was clearly correct. Throughout most of 1991, Mrs O'Hara was treated intensively for her cardiac problems. Replacement of her mitral prosthesis was necessary. Preliminary investigations of her coronary arteries were required. The surgical procedure in October 1991 was successful.

**7.182** The question can be posed whether reliance on the test results of November 1990 had a significant and adverse effect on Mrs O'Hara's management. There is no evidence that management decisions were taken on the basis of the test results. It is of course clear that, had a positive and accurate result been reported, it is likely that a management plan would have been developed that took account of that finding. Not least, it would have had an influence on surgical procedures in 1991, given the potential risk of accidental transmission from patient to staff. It would have been a positive indication that, following her cardiac care, Mrs O'Hara would have required active care by gastroenterologists. On the basis of his earlier comments, Dr Morris would have wished a biopsy, for example. It does not follow that the negative finding prevented further gastroenterological input: it did not, in fact, as the narrative of follow-up arrangements into early 1991 shows.

**7.183** Dr Mutimer was asked about the absence of gastroenterological involvement in the period between 1990 and 1995.<sup>361</sup> Whilst he initially observed that Mrs O'Hara should have 'remained in their domain', he was not critical, in all the circumstances, of the fact that this did not happen. That view is accepted. Mrs O'Hara was in the care of the cardiac department and was regularly monitored in hospital.

<sup>361</sup> Day 3, pages 34 and 51

### ***Further investigation following introduction of second-generation anti-Hepatitis C tests***

**7.184** Against this background, it is appropriate to return to the core participants' second question: whether consideration should have been given to further investigation once the second generation of anti-Hepatitis C tests had become available in September 1991.

**7.185** As discussed in Chapter 31, *The Introduction of Screening of Donated Blood for HCV*, in the period between the first anti-Hepatitis C test released for evaluation in November 1989 and September 1991, there were significant developments in technology relating to anti-Hepatitis C testing.<sup>362</sup> A pharmaceutical company, Ortho, intimated to Professor Cash, SNBTS, and Dr Gunson, NBTs, in November 1989, that their ELISA<sup>363</sup> had received an export permit from the US Food and Drug Administration that would allow the use of the test for diagnostic use. By December 1989, the West of Scotland BTS had arranged to receive Abbott Laboratories' test kits for evaluation. The lack of a confirmatory test at that time was a factor that contributed to delay in introducing the tests routinely. Ortho's first generation RIBA<sup>364</sup> confirmatory test was sent to the United Kingdom for evaluation in February 1990. The recipients included Dr Follett at Ruchill Hospital in Glasgow. Ortho's second generation ELISA, with improved sensitivity, was anticipated in a marketing announcement in October 1990 and at a scientific symposium in November 1990. The availability of second generation Ortho kits for evaluation was intimated to the Advisory Committee on the Virological Safety of Blood on 21 November 1990. By then Abbott had further developments in hand. Their test was launched on 6 December 1990. In Scotland, anti-Hepatitis C screening of blood donations was introduced generally on 1 September 1991.

**7.186** The type of Hepatitis C test used in Mrs O'Hara's case is not identified in the hospital laboratory reports.<sup>365</sup> It was carried out at the GRI Microbiology Department on the instructions of Dr Morris and reported on 18 December 1990. Having regard to the chronology above, it appears highly likely that it used one or other of the less developed test systems then available. That was Dr Cameron's evidence: she informed the Inquiry in her letter that the test would have been the first generation Ortho test.<sup>366</sup> Lack of sensitivity and specificity had been material factors in delaying the introduction of the test systems for general use. Locally, Dr Dow and others had reported in December 1989 that the Ortho Hepatitis C ELISA kit then commercially available had an acceptable specificity but an apparent reduced sensitivity compared with the development model they had previously tested.<sup>367</sup>

**7.187** Improvements in technology in the course of 1991, leading to the general adoption of anti-Hepatitis C screening of blood donations in September, might have been expected to persuade gastroenterologists, if confronted by a patient's continuing pattern of deranged LFTs, to have submitted blood for further virus serology testing.

**7.188** However, Mrs O'Hara was not in the care of the gastroenterologists at the material time and there was nothing to trigger a reference by the cardiac surgeons back to gastroenterology when her cardiac treatment was completed. It is recorded that, on

her discharge from hospital in October 1991, following her heart valve replacement, her LFTs were normal. Consideration could only have been given to further investigations following the availability of second-generation anti-Hepatitis C tests if there had been in place mechanisms (which were never defined in the evidence) to secure the continuing involvement of relevant specialists in her care and management. There is no basis in the evidence before the Inquiry for a need, separate from arrangements for Mrs O'Hara's management while in gastroenterology care, to give consideration to further investigation related to the particular development of second-generation tests.

**7.189** So far as the evidence discloses, there was no mechanism by which a former patient could be identified by a hospital following on a scientific development that might have a bearing on the patient's care or treatment and, on the initiative of the hospital, brought in for further investigation. Having regard to the obvious impracticability of implementing such an arrangement, it would not be appropriate for the Inquiry to make any recommendation that such a mechanism should be introduced.

### **Mrs O'Hara's management to late 1995**

**7.190** When admitted to the GRI on 25 February 1991, Mrs O'Hara had cardiac issues and she also had increased hepatomegaly, suggesting progressive enlargement of the liver, and her liver was slightly tender. In Dr Mutimer's view, these findings were not of themselves necessarily indicative of developing liver disease. At that stage, her cardiac problem could have caused congestion of the liver and could have contributed to her enlarged tender liver or the enlargement of her liver could have represented intrinsic liver disease, now known to be due to the inflammation of Hepatitis C.<sup>368</sup>

**7.191** Mrs O'Hara required cardiac care in the first half of 1991. As noted above, there is no basis for criticism of the decision to refer her to the cardiac clinic at that time. If there is a problem, it arises from the fact that there was no engagement of the gastroenterologists in her management after March 1991. The substantive issue focused in the first question<sup>369</sup> is whether, in light of what was known at the time, and what developed during and after cardiac care, it was appropriate for her management to proceed without further advice from gastroenterologists after 1990 and, specifically, whether it was for gastroenterology to take the initiative and call her for review.

**7.192** This issue has to be considered against the background of what was generally a good standard of management at the time. Dr Mutimer was asked whether, having regard to the medical records, there was 'someone missing from the team' from 1990, such as a gastroenterologist or a liver specialist.<sup>370</sup> The underlying concern was whether Mrs O'Hara's care might have been inadequate up to May 1995. He said:

She has got a good diabetic specialist and a good cardiologist, I think. They are probably very well trained physicians in the early 90s. They probably have very good background training in general medicine, including gastroenterology. So I don't have any reason to criticise any of the doctors who have been involved with her care so far ... It has taken a long time to get to the right diagnosis and to say what the stage of the disease is.

---

<sup>368</sup> Day 3, page 37

<sup>369</sup> Whether, following the negative Hepatitis C result in 1990, and against the background of findings of abnormal LFTs, Mrs O'Hara's liver condition should have continued to be monitored by Gastroenterology: paragraph 7.173

<sup>370</sup> Day 3 pages 49–50

[T]here have been a number of doctors at a number of hospitals who have been involved and eventually they have got there ....<sup>371</sup>

**7.193** He commented further:

[I] think again, if there had been no background cardiac problems, this probably would have come to a correct diagnosis much more quickly but this lady has been distracted by the need for, really quite major cardiac surgery, and it has also muddied the thinking about the cause of her abnormal liver function tests. So I can understand the delays that we see in establishing the correct diagnosis. It could have been diagnosed more quickly but I can understand why it took as long as it did.<sup>372</sup>

**7.194** Until 1994 Mrs O'Hara reported no problems relevant to possible liver disease at annual review. It was in August 1994 that the condition of her liver again came to the fore.

**7.195** As noted above, Mrs O'Hara frequently attended her GP in 1991, 1992, 1993 and 1994. On 17 June 1994 a diabetic assessment was noted as required and a blood test was taken.<sup>373</sup> The first LFTs noted in the GP records were reported on 9 February 1995 and were then normal.<sup>374</sup> No entry in the GP records raised an issue about Mrs O'Hara's liver or suggested a need for referral to gastroenterology.

**7.196** Given Dr Mutimer's opinion of the position at 25 February 1991, it cannot be said that the views expressed in Dr Morris' letter of 5 November 1990 were untenable.<sup>375</sup> Dr Mutimer's evidence was careful and balanced and it was not contradicted or qualified by any other evidence. Mrs O'Hara was a difficult case, given her history and the range of symptoms and signs presented. In retrospect, and in the light of Dr Mutimer's evidence, it is unfortunate that Mrs O' Hara was not monitored by gastroenterologists between early 1991 and July 1995. Had such monitoring occurred the progression in her liver disease might have been identified.

**7.197** Leaving aside the possibility that a different course of management might have been followed, there is a question whether Mrs O'Hara's Hepatitis C might have been diagnosed earlier in the course of her cardiac care. In Dr Mutimer's view, she was a patient with abnormal liver function and a patient who probably had significant liver disease.<sup>376</sup> As stated in his letter of 5 November 1990, Dr Morris thought that her cardiac problems did not entirely explain her liver problems. Liver disease was not investigated further, however, until she was referred back to the diabetic day unit at Stobhill in August 1994.

**7.198** By that time, there had been a number of specialists involved in her care, and the focus since 1991 had been on her cardiac problems. Dr Mutimer thought that the hepatosplenomegaly noted in August 1994 was not, as the consultant physician at the time thought, possibly secondary to her mitral valve replacement. It was, he considered, much more likely that this showed liver damage.<sup>377</sup> He thought that there had possibly been some crossing of wires and that perhaps investigations that had been performed

<sup>374</sup> [OHA.001.2088] at 2289. The exception relating to Gamma GT is insignificant for this purpose.

<sup>375</sup> Letter from Dr Morris to GP dated 05 November 1990 [OHA.001.2535]; discussed at paragraph 7.104

<sup>376</sup> Day 3, page 34

<sup>377</sup> Ibid pages 38–39

previously had gone out of focus.<sup>378</sup> Once Mrs O'Hara's heart was in good condition, however, people began to pay more attention to the enlargement of the liver and spleen. Matters began to develop thereafter.

**7.199** In the circumstances that developed in 1994 and 1995, it is likely that the cardiologists would be looking for a cause of the enlargement of the liver and spleen other than her cardiac surgery. Dr Mutimer said:

I think in 1994 it is two or three years after she had a successful valve replacement? So I would be surprised if the cardiologist would accept responsibility for the enlargement of the liver and spleen. And I think it is much more likely that this is showing disease of the liver and then the enlargement of the spleen is almost certainly due to that. So it all points to the likely presence of cirrhosis at this stage, with portal hypertension, in other words pressure building up behind the liver, and that includes enlargement of the spleen.<sup>379</sup>

**7.200** It appears that particular interest in Mrs O'Hara's problem among members of the GRI's cardiac team may have been generated by Dr McLaren's letter of 5 August 1994.<sup>380</sup>

**7.201** Dr Mutimer thought that the management plan developed after review at Stobhill cardiology clinic in March 1995 was entirely acceptable at that stage.<sup>381</sup> However, the investigation did not run smoothly. As noted above in paragraph 7.126, significant hepatosplenomegaly and, in particular, splenomegaly were found but, in his letter dated 12 May 1995, Dr Dunn suggested that the condition of her lymph nodes might have a malignant source, for example lymphoma. Dr Mutimer thought that this reflected lack of knowledge of underlying clinical details: this was simply a case of cirrhosis due to Hepatitis C. Lymphoma was a possibility, but not likely<sup>382</sup> and it proved to be a false trail.

#### Dr Forrest

**7.202** A new phase in Mrs O'Hara's treatment began with her referral to Dr Forrest. His response to the referral is set out at paragraph 7.136. Dr Forrest's report of 3 November 1995, based on her care records, noted hepatosplenomegaly from 1990 and biopsy evidence of established cirrhosis.<sup>383</sup> It commented on possible alternative aetiologies and it commented on the possibilities of treatment at the Royal and the Western Infirmarys, Glasgow, if the cirrhosis was due to Hepatitis C. He was not committed to a view that Mrs O'Hara's cirrhosis was due to Hepatitis C and doubted whether she was a candidate for Interferon treatment. He said he would arrange to review her liver biopsy. He was asked for further advice in March 1996 and reminded of that request in May 1996. On 10 July 1996, he reported his view that Mrs O'Hara probably had cirrhosis and a very mild continuing hepatitis.<sup>384</sup> He estimated the prospects of success with Interferon at 20–25% after prolonged treatment. He indicated that he was prepared to refer Mrs O'Hara to gastroenterologists at the Glasgow Western Infirmary for consideration of the then-new treatment with Interferon, which he described in his letter as having been funded on a 'limited basis'. He had still not seen Mrs O'Hara.

<sup>380</sup> Letter from Dr McLaren, Stobhill to GRI dated 05 August 1994 [OHA.001.1135]; discussed at paragraph 7.114 above.

<sup>381</sup> Day 3, page 46

<sup>382</sup> Ibid pages 47–48

<sup>383</sup> Dr Forrest's letter [OHA.001.1003]

<sup>384</sup> Letter from Dr Forrest to Dr McLaren [OHA.001.1017]

**7.203** Dr Mutimer commented:

There is an elephant in the room, isn't there? So I would have thought it is all due to Hepatitis C, really. I'm not sure why he is suggesting that Hepatitis C is present but not responsible for the damage. That's not likely.<sup>385</sup>

**7.204** Dr Mutimer's criticism of Dr Forrest's observations is accepted. Dr Mutimer considered that the link between Mrs O'Hara's symptoms and her Hepatitis C infection ought to have been obvious. The other possible explanations canvassed were not.

**7.205** Dr Mutimer was broadly supportive of the line taken by Dr Forrest at this time relative to treatment, however.<sup>386</sup> He thought that Dr Forrest's estimates of possible success with Interferon, an estimated success rate of 25% overall, were optimistic, both generally and in the context of the treatment of patients with advanced liver disease. He did not think that data would have existed in 1995 for Dr Forrest to have made a more accurate estimate.<sup>387</sup> Mrs O'Hara had low prospects of a good outcome from treatment. She would not have been treated by Dr Forrest, however. Concentration of Interferon treatment in particular centres was common at the time and that was not surprising.<sup>388</sup> The drugs were expensive and there was a policy of restricting their use to a limited number of centres.<sup>389</sup> Mrs O'Hara would have been referred to Dr Morris, who had by then been appointed as a consultant and was running the treatment service.<sup>390</sup> In retrospect, Dr Mutimer thought that Mrs O'Hara was probably lucky that she did not have Interferon treatment: he suspected that she would have had a lot of side-effects and no success from the treatment.<sup>391</sup> Cardiac disease was probably also a counter-indication to Interferon treatment.<sup>392</sup> Review of the biopsy was an appropriate step, to satisfy the gastroenterologist that he agreed with the pathologist's views.<sup>393</sup>

**7.206** Mrs O'Hara's daughter, Ms Annette McDonald, was a nurse at Stobhill. She asked for further information for Mrs O'Hara, probably during or shortly after her admission for liver biopsy in June or July 1995.<sup>394</sup> A doctor saw Mrs O'Hara with Ms McDonald and they were told that Mrs O'Hara had Hepatitis C as well as cirrhosis.<sup>395</sup> The family knew that when cirrhosis was established it was possibly too late to do anything.<sup>396</sup>

**7.207** Dr Forrest had an opportunity to see Mrs O'Hara at this time; he did not do so. Another opportunity arose in July 1996 when he again reviewed her case; again he did not do so. Dr Mutimer was critical of Dr Forrest for carrying out only a 'desk-top' review of Mrs O'Hara's case in July 1996. The planned management that was developed was appropriate but Dr Mutimer thought that what might be missing was the chance to actually see the patient and to discuss her illness and the reasons why treatment was not suitable.<sup>397</sup>

<sup>395</sup> Mrs Kennedy – Day 3, page 5; The doctor cannot be identified. This was probably an informal meeting and was not recorded at the time, so far as Stobhill's records show.

<sup>396</sup> Mrs Kennedy – Day 3, page 15

<sup>397</sup> Day 3, pages 61–62

**7.208** It also deprived Dr Forrest of the advantages that might reasonably have been expected to accrue from direct contact with the patient to discuss her history.

**7.209** Dr Mutimer's opinion that it would have been good practice for Dr Forrest to have seen Mrs O'Hara was clearly correct. Any patient would have benefited from an explanation of his or her condition and of why the forms of treatment that were available at the time were not suitable or were unlikely to be effective in his or her case. Given Mrs O'Hara's interest in obtaining explanations and information, this was not a case in which it might have been thought that there would be a disinclination to have the true position spelled out. She was, as were her daughters, 'mining' for more information about the implications for Mrs O'Hara of her infection.<sup>398</sup>

**7.210** Dr Forrest's reports do not appear to have been copied to Mrs O'Hara's GP. He did not, therefore, make provision for informed discussions between Mrs O'Hara and her GP. However, at this time patients would have been dependent on specialist knowledge of Hepatitis C: it was not a subject that most GPs would have known about.<sup>399</sup>

**7.211** Dr Forrest died on 26 June 2010, and it was not possible to have his observations on this chapter of evidence.

### **Counselling and information**

**7.212** A further issue raised by Mrs O'Hara's case relates to the failure to provide appropriate counselling and support for her Hepatitis C and its consequences after the diagnosis had been made in the summer of 1995. A particular complaint is that Mrs O'Hara was not told about the danger of secondary infection and appropriate precautions.<sup>400</sup>

**7.213** In the context of the look-back exercise begun in April 1995, a document entitled *Transfusion-transmitted Hepatitis C: Guidelines for Counselling Patients* was widely available to those engaged in tracing recipients of blood or blood components from donors known to be carriers of the Hepatitis C virus.<sup>401</sup> The purpose of look-back, discussed in more detail in Chapter 35, *An Investigation into the Steps Taken to Identify the Individuals Who Were Infected (Look-Back)* was to trace NHS patients who had received blood, blood components or blood products derived from donations by donors who tested positive for Hepatitis C antibodies after 1 September 1991, when screening was introduced, and who had previously donated blood which was found by retrospective testing also to have been infective. The document provided background information on transfusion-transmitted Hepatitis C infection, the discovery of the virus and the development of tests for it. Among the modes of transmission highlighted were: sharing needles during intravenous drug misuse; transfusion; tattooing and other skin-piercing procedures; and, to a limited degree, sexual transmission. Hepatitis C positive individuals were advised that they should not donate blood. They should not share toothbrushes or razors and they should inform dentists and doctors of their HCV status. Information was given about Alpha Interferon, the only licensed therapy for chronic Hepatitis C at the time. The document was not intended for patient use but it provided one measure of what might reasonably have been expected in counselling an infected individual at the time Mrs O'Hara was told that she had Hepatitis C and cirrhosis in the summer of 1995. She was never counselled along the lines of the document.<sup>402</sup>

<sup>401</sup> Transfusion-transmitted Hepatitis C Guidelines [LAI.001.0020]

<sup>402</sup> Mrs Kennedy – Day 3, pages 9–12

**7.214** Mrs O'Hara was a person with clearly expressed concerns about her health and an anxious wish to have any treatment that was available. She found having Hepatitis C very difficult. Some of her concerns were created unnecessarily by inadequate and inaccurate information.

**7.215** Mrs Kennedy said they were all shocked when a doctor at Stobhill said that blood had been taken from American prisoners and that this might be a source of Hepatitis C.<sup>403</sup> This was a misapprehension on the part of the person who gave the information. The Inquiry has seen evidence that some commercial large-pool Factor VIII blood products imported into the UK in the 1970s and 1980s were manufactured from plasma that included donations from prisoners. No whole blood used for transfusion in Scotland was collected outwith Scotland, however. The infected blood in Mrs O'Hara's case was donated in Scotland.

**7.216** Other misapprehensions are less easy to deal with. Mrs Kennedy said that her mother hated having 'Hep C risk' stamped on the front of her medical notes and was embarrassed. She knew that Hepatitis C was an infection usually associated with drug addicts. She was well known in Stobhill, having worked there, and was worried that people might find out. She felt that the comment should have been concealed inside her notes.<sup>404</sup> However, none of the Stobhill records the Inquiry has recovered are so stamped and the two volumes of GP records both have the 'Special Hazards' section on the front page left blank. Certain sheets within the GP records are headed 'Hep C Risk'. The basis for apprehension that people in Stobhill might find out about her infection cannot be verified, although it was clearly real for Mrs O'Hara.

**7.217** Mrs O'Hara's other daughter, Ms Annette McDonald, asked for further information for her mother, probably in June or July 1995. The doctor who saw Mrs O'Hara with Ms McDonald said that Hepatitis C had possibly caused cirrhosis of the liver and that she had probably contracted Hepatitis C from a blood transfusion. Their impression at the time was that the doctor played down the significance of Hepatitis C and implied that it was a common infection: cirrhosis was a lot more serious.<sup>405</sup> No advice was given about avoiding transmission or about her blood.<sup>406</sup> There was no offer of counselling or further information.<sup>407</sup> Mrs O'Hara asked about possible treatment for Hepatitis C. She was told there was no treatment as she already had cirrhosis.<sup>408</sup> Mrs Kennedy said:

[I] think when you have been attending hospitals, you do ask about treatments because it has been your experience that usually something can be done, you know, when you have had heart problems. So we just wondered, and I know my mum wondered, if just anything could be done because she was very used to following doctor's instructions and she was very faithful to doctor's instructions, and I think she just thought if there was something she could do things might get a wee bit better.<sup>409</sup>

<sup>407</sup> Ibid [WIT.003.0420] at 0422

<sup>408</sup> Ibid [WIT.003.0420] at 0423

<sup>409</sup> Day 3, page 7

**7.218** In April 1998, Mrs O'Hara again asked about Interferon treatment, based on her reading of media reports.<sup>410</sup> The haematologist who saw her on 20 April left it to her GP to decide whether to re-refer her to the gastroenterologists. There is no record of her having been re-referred for gastroenterological opinion at this time.<sup>411</sup> The issues raised by her care down to mid-1997 were not resolved.

**7.219** Except in relation to counselling relating to Mrs O'Hara's cirrhosis and the treatments that might have been available for it in her case, the complaints of Mrs O'Hara's family do not lend themselves to easy categorisation. The casual mis-information provided by an unidentified doctor about the source of blood would clearly have upset the family – but it had, and could have had, nothing to do with Mrs O'Hara's treatment. Her concern about entries in her Stobhill records referring to 'Hep C risk' would again be completely understandable given her long association with the hospital but the apprehension was not well founded in fact: the hospital records were not so marked.

**7.220** Once Mrs O'Hara's cirrhosis was diagnosed, the appropriate source of accurate information about her condition, its prognosis, and counselling in relation to any particular treatment was Dr Forrest, the Consultant Gastroenterologist to whom her case was referred in September 1998. He had the opportunity to provide both information and counselling, either directly to Mrs O'Hara or by copying his inter-departmental letters to the GP for the benefit of Mrs O'Hara. Generally, there was the model of the look-back guidance as a source of what was required for the benefit of the patient.

**7.221** It has been submitted that the treatment of Mrs O'Hara raises a systemic issue about the provision of counselling and support of patients with Hepatitis C. That there were deficiencies in her case is clear but there is no basis in the evidence as a whole for a view that these were due to any systemic failure. There were lapses attributable to an individual, Dr Forrest, but it cannot be found on that basis that there was a fundamental defect in the hospital's general procedures. Mrs O'Hara's case, while of great importance to her family, is not evidence of a universal or general failure on the part of the hospitals involved, nor on the part of the NHS as a whole.

## Other issues

**7.222** The SNBTS was not able to trace the donors whose blood was transfused during Mrs O'Hara's surgery in June 1985.<sup>412</sup> The GRI Blood Bank utilised an Apple computerised system from 1981–86. It has been explained that the Apple system could not accept the SNBTS donation number configuration. The GRI laboratory allocated an identifier that was entered into the Apple system and those records contained no cross-references to the SNBTS pack numbers. A paper record was kept of the respective numbers but the paper records for 1985–86 were destroyed in error during a laboratory move in 1995.<sup>413</sup> There are no extant records that would link the units used in Mrs O'Hara's case with the SNBTS unit numbers.<sup>414</sup>

---

<sup>410</sup> Letter from Stobhill to GP dated 23 April 1998 [OHA.001.2249]

<sup>411</sup> Dr Mutimer – Day 3, pages 65–66

<sup>412</sup> Explanation by Inquiry Counsel – Day 1, pages 143–150; Letter from Inquiry to Susan Murray, Central Legal Office dated 10 December 2010 [PEN.010.0074]; SNBTS response – January 2011 [PEN.001.0032] at 0033; Email from Inquiry to CLO dated 03 February 2011 [PEN.002.0762]; SNBTS Supplementary response – February 2011 [PEN.002.0760]

<sup>413</sup> Letter from Dr Rachel Green, NHS Greater Glasgow and Clyde Acute Services Division to CLO dated 25 August 2011 [PEN.017.2153]

<sup>414</sup> Letter from Dr Tait, GRI Haematology to Dr Rachel Green dated 25 November 2008 [PEN.010.0106]

**7.223** The destruction of the paper record does not, of itself, raise any systemic issue for the Inquiry. Accidents occur in any system and may or may not indicate structural deficiency. Dependence on a paper record as a necessary link in the recording may be a different matter.

**7.224** While it is understandable that the limitations of a particular computer system might prevent it from accommodating, or reading automatically, an electronic number configuration generated by a different system, it is less understandable that the text of a GRI laboratory record should not contain, by such means as the computer software allowed, the link number to the SNBTS source material.<sup>415</sup> If that was not possible at that time, reliance on a paper record inevitably meant those records were vulnerable to accidental or erroneous destruction.

**7.225** The circumstances of the 'unfortunate' error have not been explained other than that it related to a laboratory move in 1995. Carefully specified protocols for the retention and destruction of records relating to patient care are a fundamental pre-requisite of sound administration of the NHS. Whether such protocols were in place and whether they were applied remain unanswered questions. Allowing two separate numbering systems in the principal records of interdependent NHS organisations, with linkage depending on paper records, questionable in itself, gives added weight to the requirement for controls.

### **Reasonable precautions whereby Mrs O'Hara's death might have been avoided**

**7.226** It was not suggested in the closing written submissions by the patient interest core participants that there were any reasonable precautions that might have been taken by which Mrs O'Hara's death might have been avoided.<sup>416</sup> There were none.

### **Cause of death**

**7.227** The cause of Mrs O'Hara's death was acute pancreatitis complicated by sepsis and multi-organ failure. Possible contributory causes were:

- Hepatitis C virus cirrhosis consequent on blood transfusion prior to 1985.
- Chronic heart failure with prosthetic mitral valve consequent upon rheumatic fever in childhood.
- Type II diabetes.

**7.228** The failure to record Hepatitis C as a cause of death was an error but, in the overall complex circumstances of her death, not an important error. It has been submitted that this reflects a systemic defect in procedure. While there are indications elsewhere of disinclination on the part of some doctors, and some families, to have Hepatitis C recorded (as occurred also in the case of HIV/AIDS) there is no evidence that the failure in this case was attributable to any policy or widespread practice.

<sup>416</sup> Closing submissions of patient interest core participants (para 3) [PEN.019.0779]

## Conclusions

### 7.229 Infection with Hepatitis C and progression of disease:

- (i) While nosocomial transmission of the Hepatitis C virus cannot be excluded absolutely, it is highly likely that Mrs O'Hara was infected by blood transfusion.
- (ii) The most likely date of infection was 28 November 1979 when Mrs O'Hara received a transfusion in the course of a hysterectomy.
- (iii) Mrs O'Hara was tested for Hepatitis C infection by first-generation Ortho ELISA on 5 November 1990, with negative result.
- (iv) The test result was a false negative.
- (v) Mrs O'Hara developed cirrhosis due to infection with the Hepatitis C virus.
- (vi) Insofar as Hepatitis C contributed to her death (and the extent of that contribution cannot be resolved with any confidence) her infection with the virus in 1979 could not have been prevented.
- (vii) The failure to record Hepatitis C as a cause of death was an error but, within the context of the complex circumstances of Mrs O'Hara's death, not an important error. It was not found to be a systemic defect in procedure.

### 7.230 Mrs O'Hara's management as a patient:

- (viii) It is impossible to form a view on the evidence as a whole that there was reliance on the test results relating to the blood samples taken in November 1990 which had or may have had a significant and adverse effect on Mrs O'Hara's management in 1990–91.
- (ix) Mrs O'Hara had a complex medical history and, in particular, in 1990–91 had serious heart disease that warranted surgery.
- (x) The gastroenterologists in charge of Mrs O'Hara's care at the end of 1990 referred her to the GRI Cardiology.
- (xi) That decision was well founded, given their findings on examination and investigation. The diagnosis of congestive cardiac failure was sustainable.
- (xii) The actions of the gastroenterologists, and in particular Dr Morris, including arranging a follow-up appointment for early 1991, suggest that the test results were not treated as definitive at the end of 1990 and in early 1991.
- (xiii) Continuing gastroenterological supervision of Mrs O'Hara's case was interrupted in March 1991 when contact broke down.
- (xiv) It is not possible to conclude, on the evidence as a whole, whether, if Mrs O'Hara had attended the appointment with gastroenterology on 11 March 1991, further examination by gastroenterologists would have changed the course of her management: that would be speculative.
- (xv) Mrs O'Hara was receiving comprehensive cardiology care at the time and non-attendance was considered to be understandable. The records do not disclose follow-up at gastroenterology.
- (xvi) When discharged from hospital in October 1991, Mrs O'Hara's liver function tests were normal.

(xvii) Having not attended gastroenterology in March 1991, Mrs O'Hara's liver condition was not monitored systematically between 1991 and 1994.

(xviii) Mrs O'Hara remained asymptomatic of anything to suggest chronic liver disease until August 1994 and her liver function tests were at least sometimes within her normal range. There was nothing to stimulate interest in her liver condition until Dr McLaren raised the issue in August 1994.

(xix) Since Mrs O'Hara was not receiving care related to liver disease between September 1991 and August 1994, and had not reported signs and symptoms giving rise to concern about her liver, there were no grounds for referring her for testing with second-generation anti-Hepatitis C tests when they became available.

### **7.231** Counselling and information

(xx) There was a significant lapse in Mrs O'Hara's management as a patient after she was referred to Dr Forrest on 11 September 1995.

(xxi) Dr Forrest's initial review letter dated 3 November 1995 is not criticised as unduly delayed but he carried out a review of records without seeing Mrs O'Hara.

(xxii) A request for further review was sent to Dr Forrest in March 1996. He responded on 10 July 1996, again without seeing Mrs O'Hara.

(xxiii) Taken together, these periods amounted to unacceptable delay on the part of Dr Forrest in responding to the referral and a failure in management attributable to his repeated 'desk-top' disposal of issues relating to Mrs O'Hara.

(xxiv) Mrs O'Hara should have had an opportunity to meet Dr Forrest and discuss her condition and the reasons for his opinion that Interferon treatment was not considered suitable in her case.

(xxv) Mrs O'Hara should have been given advice and counselling about her Hepatitis C status along the lines of the April 1995 document: *Transfusion-transmitted Hepatitis C: Guidelines for Counselling Patients*.

(xxvi) She did not receive any such counselling and advice. Dr Forrest was in a position to tender counselling and advice and should have seen Mrs O'Hara for that purpose. These deficiencies in Mrs O'Hara's management as a patient were attributable to Dr Forrest, stemming from his failure to see Mrs O'Hara in person, and did not evidence a universal or general failure on the part of the hospitals involved, nor on the part of the NHS as a whole.

## **Alexander Black Laing**

### **Introduction**

**7.232** Mr Laing was born on 7 December 1923. He died on 4 September 2003. The certified cause of death was 'Hepatitis C Related Liver Disease'.<sup>417</sup>

**7.233** Mr and Mrs Laing were married in 1951. Mr Laing was, prior to retirement, a linesman with the North of Scotland Hydro Electric Board and its successors. He retired in 1985.<sup>418</sup> As with all of the deaths remitted for inquiry in Term of Reference 6, it is important to provide information that may help Mrs Laing and her family understand the

---

<sup>417</sup> Death Certificate [LAI.001.1068]

<sup>418</sup> Witness Statement of Mrs Annie Laing [WIT.003.0417]

background to Mr Laing's infection and ultimate death. On a more general level, however, his experience illustrates the natural history of Hepatitis C infection in a man who, at the time of infection, was older than others investigated. It is also an illustration of exemplary care.<sup>419</sup>

## Mr Laing's medical history

### *Surgery in 1990*

**7.234** Mr Laing had surgery at the Aberdeen Royal Infirmary (ARI) on 7 August 1990. He was 66 at the time. The diagnosis was Duke's C carcinoma, indicating that the cancer had infiltrated through the bowel.<sup>420</sup> The tumour had moved beyond the local territory of the bowel and penetrated one of the seven lymph glands which were sampled at operation and examined microscopically. The fact that the cancer had penetrated one only of those lymph glands offered a slightly better prognosis than had it penetrated more than one. It was, nevertheless, a cancer with a poor prognosis in the longer term and a high chance of recurrence.<sup>421</sup> In the event, Mr Laing made a good recovery.<sup>422</sup>

**7.235** In the course of surgery Mr Laing received blood transfusions. He received two units of whole blood and other blood components and products.<sup>423</sup> The transfusion of whole blood is relevant for the purposes of this Report as it was capable of transmitting Hepatitis C infection. At the end of a course of out-patient care following surgery, lasting some five years, Mr Laing was told that the cancer was clear but that he had contracted Hepatitis C infection from the blood transfusion.<sup>424</sup> Mr Laing had been identified as being at risk by the UK-wide look-back exercise into transfusion-related Hepatitis C virus (HCV) infection which was in progress in 1995.

### *Hepatitis C look-back*

**7.236** The purpose of look-back was to trace NHS patients who had received blood, blood components or blood products derived from donations by donors who tested positive for Hepatitis C antibodies after 1 September 1991, when screening was introduced, and who had previously donated blood which was found by retrospective testing also to have been infective. Formal written intimation that Mr Laing had been so identified was given in a letter from the Scottish National Blood Transfusion Service (SNBTS) to his GP dated 26 April 1995. Enclosed with the letter was a form for the assessment of Mr Laing's suitability for counselling. The form was completed by the GP on 28 April.<sup>425</sup> Procedures for managing the exercise had been developed on a national, UK-wide basis by a steering group of which Dr Graeme Alexander, Consultant Hepatologist, Addenbrookes NHS Trust, Cambridge, was chairman.<sup>426</sup>

<sup>424</sup> Mr Laing was so told by his surgeon at ARI, according to witness statement of Mrs Annie Laing [WIT.003.0417] and/or by his GP according to letter from the GP to him dated 6 June 1995 [LAI.001.0102]

<sup>425</sup> Letter from Aberdeen and North East Scotland BTS (SNBTS) to GP dated 26 April 1995 [LAI.001.0105]; Assessment form [LAI.001.0103]

<sup>426</sup> Dr Alexander – Day 4, pages 9–10

**7.237** The look-back exercise will be discussed in greater detail in Chapter 35, *An Investigation into the Steps Taken to Identify the Individuals Who Were Infected (Look-Back)*. At this stage, it is sufficient to note parts of the wider context. In the South East of Scotland Blood Transfusion Service, a local exercise had demonstrated that look-back was feasible. Scottish Health Ministers were persuaded by December 1994 that there should be a look-back exercise for Scotland as a whole. In England and Wales, proposals for a look-back study began to be considered almost as soon as Hepatitis C testing showed that some blood donors tested positive. Dr Alexander's group had started working in 1992–93.<sup>427</sup> However, until December 1994 the proposal was controversial. Objections were overcome by the end of the year and look-back was commenced throughout the UK in 1995.

**7.238** Dr Alexander said that the majority of Hepatitis C positive blood was donated by individuals who had, at some time in the past, used illegal drugs.<sup>428</sup> Over a long period, people with a history of intravenous drug use were asked not to give blood. Standard procedure at donation sessions before September 1991 included inspection of prospective donors for physical evidence of their having injected drugs. Drug use resulting in donor infection might have occurred many years earlier and been forgotten, however, or, in the absence of signs and symptoms of disease, may have been dismissed as irrelevant by the donor. Apart from physical inspection, investigation of the history of the prospective donor was inconsistent and seldom involved questioning in depth.<sup>429</sup> Practice improved in and after 1982 in response to the threat of AIDS but, as Dr Alexander's findings indicate, individuals with a history of intravenous drug use still made up the majority of those testing positive for Hepatitis C after September 1991.

**7.239** Another cohort of infected donors acquired Hepatitis C infection from blood transfusion, again in some cases many years earlier. In 1991–92, when Hepatitis C screening of donated blood began, Dr Alexander and his colleagues were surprised at how many blood donors coming to sessions tested positive: they had not anticipated that quite as many people might have acquired Hepatitis C from transfusion.<sup>430</sup> The majority of individuals with Hepatitis C infection, whether acquired by injecting drugs or by transfusion, did not become ill at the time of infection with the virus. Whether knowingly or not, some people potentially infective with Hepatitis C continued to give blood.

**7.240** At follow-up as part of the look-back exercise, it was ascertained that the donor in Mr Laing's case had received a blood transfusion around 20 years previously.<sup>431</sup> This was the only risk factor attributable to that particular donor. In his evidence, Professor Marc Turner, Medical Director of the SNBTS, outlined the approach to this risk factor. Deferral<sup>432</sup> of donors who had themselves received blood transfusion was not introduced in the UK until 2004. At that time, the SNBTS initiated deferral of donors who had received a blood donation since 1980. The measure was related to the risk of transmission of variant Creutzfeldt-Jakob disease (vCJD). The only other country of which Professor Turner was aware which defers donors permanently because they have themselves had a blood transfusion is France, where such a measure was introduced in 1997.<sup>433</sup>

### *Counselling and forward planning*

**7.241** After the UK national look-back programme was initiated, the focus was on previous blood donors returning to make donations. If found to be Hepatitis C positive on return, it was assumed that the donor might also have been positive at the time of donations made before screening had started.<sup>434</sup> Recipients of any earlier donations could then be identified and approached with a view to counselling and testing to determine their Hepatitis C status. In Scotland, if the patient's GP was willing to undertake that role, the SNBTS would provide details of the blood samples needed and where these should be sent, and also offer any further support or advice required. If, on the other hand, the GP wished the Blood Transfusion Service to notify and counsel the patient, the SNBTS was happy to do that. It was recognised that it might not be advisable to tell some patients and provision was made for that situation.<sup>435</sup>

**7.242** Mr Laing's GP, Dr Lynch, elected to undertake his care in this regard and sought advice from the SNBTS.<sup>436</sup> On 31 May 1995, he was sent copies of the nationally agreed counselling guidelines and a form to report the outcome of the process.<sup>437</sup> Dr Lynch wrote to Mr Laing on 6 June 1995 inviting him to make an appointment.<sup>438</sup> On 27 June he again asked Mr Laing to call as the results of the blood tests had been received.<sup>439</sup> Dr Lynch saw Mr Laing and told him the outcome. He then wrote to Dr Yates, consultant at the North East Scotland Blood Transfusion Centre at the ARI, noting that the Hepatitis C antibody and confirmatory tests were positive, providing current liver function test results, which were abnormal, and noting:

I have told him that he seems to have contracted Hepatitis C from his transfusion 5 years ago and that it may or may not damage his liver and that he will be seeing a Specialist to advise about the possibility of Interferon or not. He accepts all this with equanimity.<sup>440</sup>

**7.243** Dr Alexander considered that a fair forward plan had been established.<sup>441</sup> Mr Laing was referred for hospital care at the gastrointestinal clinic.<sup>442</sup> His general health was reported to be perfect and he was said not to have hepatomegaly (enlargement of the liver). He was seen quite promptly in July 1995 and examinations were carried out on 15 August and reported to his GP. At that stage, Mr Laing was thought to have an asymptomatic infection with Hepatitis C attributed to the blood transfusion in 1990. He was not jaundiced and had no other stigmata (signs) of liver disease. Liver function tests were repeated and a PCR (polymerase chain reaction) test performed to confirm that he was still harbouring the virus. The history of Duke's C carcinoma was thought to be a problem and further tests were instructed<sup>443</sup> as it appears to have been thought that cancer might have recurred.<sup>444</sup> It was thought that Interferon therapy might be of no use to him.<sup>445</sup> In retrospect, Dr Alexander thought that the reasoning about cancer was

<sup>444</sup> Dr Alexander – Day 4, page 16

<sup>445</sup> Letter from ARI to GP dated 24 August 1995 [LAI.001.0095]

suspect but that the right decision had nonetheless been reached about treatment.<sup>446</sup> In 1995 clinicians did not have good insight into the natural history of Hepatitis C, particularly in the older age group of patients. The evidence at that time suggested that there was a 10–20 year lag before cirrhosis would be established.<sup>447</sup>

### *Hepatitis C infection in older patients*

**7.244** Dr Alexander explained that the contemporaneous assumption about progression to cirrhosis was now known to be wrong in the case of older patients.<sup>448</sup> The common assumption in 1995 was reflected in the report by Dr Sinclair, Consultant Gastroenterologist, sent to Dr Lynch on 17 November 1995:

We now know that the long term outlook with hepatitis C is probably, in someone of this age group, fairly benign as it would probably be a significant amount of time before he produced enough chronic liver damage to creat [*sic*] ill health and my guess is that he will die of something other than liver disease. He is completely unphased [*sic*] by the whole thing but I do think we are due him a clearcut opinion as to the state of his liver and the only way to do this is with liver biopsy.<sup>449</sup>

**7.245** Dr Alexander thought that recurrence of cancer in the longer term was more likely than not, with a related risk of mortality.<sup>450</sup> At the time, however, there was no evidence of metastasis from the Duke's C carcinoma.<sup>451</sup> A liver biopsy was carried out on 25 January 1996 which showed chronic active hepatitis and gave rise to a suspicion of cirrhosis.<sup>452</sup> The tissue sample extracted on biopsy was fragmented, which may happen when the liver has significant scarring. In such cases only softer tissue comes out with the needle; scar tissue is not withdrawn with the core. The findings were therefore not absolutely reliable. Dr Alexander interpreted the pathologist's comments as reflecting suspicion that there was cirrhosis, masked by the state of the core sample withdrawn.<sup>453</sup> That impression was strengthened by the degree of liver inflammation noted. Dr Alexander thought that Mr Laing probably had cirrhosis in 1996.<sup>454</sup>

### *Clinical management*

**7.246** Mr Laing's management was discussed on 2 May 1996 at a clinico-pathological conference attended, as was typical, by the clinicians involved in the patient's care and the hospital pathologists.<sup>455</sup> That was good practice. There might be one or two or maybe up to a dozen people at such a conference. Dr Alexander speculated that there would have been a discussion suggesting that the pathologist's views were guesswork, that Mr Laing was very well, that he did not have any signs of liver disease and that there was nothing clinical to suggest cirrhosis.<sup>456</sup> It cannot be concluded that this did happen but the outcome was consistent with the hypothesis.

<sup>454</sup> *Ibid* page 22

<sup>455</sup> ARI handwritten note dated 2 May 1996 [LAI.001.0625]; Letter from ARI to GP dated 15 May 1996 [LAI.001.0087]; Dr Sinclair's report [PEN.010.0174]

<sup>456</sup> Day 4, pages 39–40

**7.247** The overall conclusion was that the patient did not have cirrhosis. The consensus that emerged was that the biopsy showed mild inflammation affecting the liver with some early fibrosis which was a different conclusion from that of the pathologist.<sup>457</sup> Dr Alexander thought that this slightly underestimated the condition.<sup>458</sup> He questioned the approach: he had always worked on the assumption that one took the worst possible news when making clinical decisions rather than the best possible news. If the pathologist was suspicious that it was cirrhosis, it was reasonable to follow his view. Others, however, worked in different ways.<sup>459</sup> Dr Alexander thought that the pathologist's report was quite clear that there were features of cirrhosis but that it would have made no difference at all to Mr Laing's clinical management had the pathologist's view prevailed.<sup>460</sup>

**7.248** Among clinicians at this time there was no enthusiasm for therapy, given Mr Laing's age, the absence of symptoms of Hepatitis C and his mildly abnormal liver function test results.<sup>461</sup> Later, in September 1996, it was thought that there might be a case for Interferon treatment and that was discussed with Mr Laing. Mr Laing's preference was to 'take his chances' and not to have treatment. Dr Lynch was asked to keep an eye on his liver function tests.<sup>462</sup> As at September 1996, Dr Alexander's data over a 10 year period showed a success rate with Interferon of less than nine per cent across the board. When the position was reviewed in about 2000–01, it was found that people over 60 did not respond at all. In addition to questions about its effectiveness, the treatment was unpleasant to administer. Dr Alexander thought that Mr Laing and his doctors had taken the right decision: on balance, Mr Laing had little to gain and a lot to lose by being treated.<sup>463</sup>

**7.249** Monitoring continued and regular blood tests were taken. Mr Laing was told that there was little that could be done for the infection and that such treatment as there was might make him worse. In Mrs Laing's words, he 'just got on with his life' but he was careful to protect his family. If he had a cut, he would warn family members to keep clear of the blood.<sup>464</sup>

**7.250** There was an unfortunate incident in September 2000 when Mr Laing needed some dental treatment and his own dentist refused to treat him because he was Hepatitis C positive.<sup>465</sup> Dr Alexander said that incidents of this kind happened all too often.<sup>466</sup> Some dentists were apprehensive that liver disease pre-disposed the patient to bleeding but there was no reference to clotting problems in the record and Dr Alexander could not assume that the dentist had made his decision on concerns about bleeding rather than a more general fear of infection transmission.<sup>467</sup>

### *The return to ill health*

**7.251** In about 2000, Mr Laing began to become tired. His appetite was poor and he developed a tremor in both hands. He slept a lot and gave up bowling.<sup>468</sup>

<sup>466</sup> Day 4, page 24

<sup>467</sup> Ibid page 25

<sup>468</sup> Witness Statement of Mrs Annie Laing [WIT.003.0417] at 0418

**7.252** In December 2001, he attended the ARI complaining of anorexia, lower abdominal and back pain, insomnia, dark urine and light stools over a period of two to three weeks. He was admitted to hospital between 8 and 11 December. Mr Laing's liver function test results were deranged. An abdominal ultrasound scan failed to reveal any relevant abnormalities, in particular in the liver. It was decided that he had had gallstones that had passed.<sup>469</sup> Nevertheless, on 31 December he was referred to the surgical out-patient department for surgical assessment on the view that gallstone disease was the underlying problem.<sup>470</sup> Dr Alexander thought that the blood tests and ultrasound results were not consistent with that diagnosis. In reaching the decision that the underlying problem was an early manifestation of liver failure, he was not influenced by the fact that no gallstones were noted in the gall bladder as they could have been missed. Rather, there was nothing to suggest that gallstones were the cause of the symptoms or the likely cause of Mr Laing's problems. The symptoms were more likely to be an early manifestation of liver failure due to Hepatitis C.<sup>471</sup>

**7.253** In addition to gallstones, the reference letter to the ARI of 31 December 2001 referred to Mr Laing's chronic active Hepatitis C.<sup>472</sup> In January 2002, Mr Laing began vomiting again.<sup>473</sup> He was seen at hospital on several occasions in January, February and March.<sup>474</sup> Vomiting persisted. The department of Biochemistry and Haematology reported on 24 April 2002 that his biochemical metrics were consistent with hepatic impairment, repeating a report of 5 December 2001.<sup>475</sup>

**7.254** On 19 November 2002, Mr Laing was referred to the breast clinic at the ARI for investigation of a swelling beneath his right nipple.<sup>476</sup> The GP was unsure of its significance. Right gynaecomastia (enlarged breast) was diagnosed. In a letter dated 18 February 2003, the consultant reported:

He does not appear to have any particular predisposing factors to gynaecomastia.

**7.255** She noted that he had reported weight loss, loss of appetite and vomiting and suggested that he might be referred back to gastroenterology.<sup>477</sup>

**7.256** Mr Laing was seen at the ARI Gastroenterology Clinic on 4 March 2003. The consultant's report of the examination to the GP stated:

He feels well with no nausea or vomiting. His breast pain has decreased. I note that he had a liver biopsy back in 1996, which suggested fibrosis and it is conceivable that he has now progressed to cirrhosis. It may be that the Gynaecomastia is associated with the cirrhosis. He has no abdominal or ankle swelling and feels well and therefore there is no indication for any further intervention at present.

**7.257** He was to be reviewed in six months.<sup>478</sup>

### ***Advanced liver disease***

**7.258** Early in June 2003, Mr Laing was so unwell he could not get out of bed to go to the toilet. He was vomiting, his abdomen was distended, his speech was slurred and he was dribbling from the mouth. Mr Laing was not a man to call the doctor but Mrs Laing did call for help.<sup>479</sup> The GP visited on 6 June and prescribed medication to settle his stomach and assist sleep. Mrs Laing contacted the GP again on 16 June.<sup>480</sup> Following examination, the GP referred him to gastroenterology at Woolmanhill Hospital, Aberdeen,<sup>481</sup> and it was arranged that he would be admitted there.<sup>482</sup> The referral letter on this occasion set out fully the GP's findings and Mr Laing's recent history; Mr Laing had gynaecomastia, thought to be due to his cirrhosis, weight loss, loss of appetite, nausea and vomiting. On examination the GP had found him to be jaundiced. He had tremor on both hands and his abdomen was distended. He had slight epigastric (abdominal) tenderness and was unsteady on his feet, among other signs and symptoms. There was a concern that his neurological symptoms of unsteadiness, including positive Romberg's sign and tremor, indicated some cerebellar dysfunction.<sup>483</sup> In the event, he was seen at the gastroenterology and liver service department at the ARI. It was reported by the clinic that he had no problems in relation to Hepatitis C and did not want to be treated.<sup>484</sup> His bloods were checked and it was noted that arrangements had been made for him to be seen at the clinic in six months.

**7.259** Dr Alexander explained that the gynaecomastia was a sign of advanced liver disease caused by excess oestrogen changing the balance of hormones in circulation. In advanced liver disease more oestrogen circulates freely and more female characteristics develop.<sup>485</sup> In his view the picture was of advanced liver failure with hepatic encephalopathy (brain disorder caused by liver dysfunction) which characteristically comes with unsteadiness of gait and tremor.<sup>486</sup> Dr Alexander considered that many of the symptoms at that time would have been readily attributable to evolving liver disease.<sup>487</sup>

**7.260** Mr Laing was seen at Woolmanhill Hospital on 2 July 2003 before being admitted to the ARI from 7 to 28 July 2003.<sup>488</sup> A Computerised Tomography (CT) scan was performed on 24 July.<sup>489</sup> Dr Alexander highlighted the significant findings from the scan. The liver was small. With most liver disorders the liver initially becomes enlarged and then, as the process evolves over years or even decades, the liver shrinks and eventually becomes too small to sustain life. In Mr Laing's case, the liver was also described as 'irregular', which meant that the surface of the liver had a scalloped contour consistent with cirrhosis. There was no focal lesion and so there was no sign of cancer. Dr Alexander was surprised that the spleen was not enlarged as it often is in advanced liver disease. Mr Laing also had moderate ascites, a collection of fluid in the abdomen, which was suggestive of liver failure and, from a clinical point of view, indicated that life expectancy was less than two

<sup>489</sup> ARI Diagnostic Imaging report dated 24 July 2003 [LAI.001.1020]

years. On this occasion he had gallstones, which were missed previously on the ultrasound scan. These features told Dr Alexander that Mr Laing had advanced liver disease.<sup>490</sup>

**7.261** Mr Laing was re-admitted to the ARI on 30 July but deteriorated rapidly.<sup>491</sup> There was a picture of steady decompensation: his condition was no longer under control.<sup>492</sup> Mr Laing now had signs that implied an increasing risk of serious disease and death including bleeding, ascites and confusion.<sup>493</sup> Mr Laing had also developed pedal oedema (swollen feet), another feature of liver disease.

**7.262** Mr Laing was not able to go home and began to fade. A decision was taken that he should not be resuscitated and palliative measures were put in place. He died on 4 September 2003 with his family at his side.<sup>494</sup>

### The natural history of Mr Laing's infection

**7.263** The certified cause of death was 'Hepatitis C Related Liver Disease'.<sup>495</sup> Dr Alexander thought it should have been liver failure secondary to Hepatitis C and cirrhosis but that it was as accurate as it needed to be for the purpose of communicating the cause of death.<sup>496</sup>

**7.264** Dr Alexander explained some of the mechanisms involved in Mr Laing's final illness. He had jaundice. Although the precise mechanism by which jaundice is caused is not very clear, essentially bilirubin (a bile pigment which is orange or yellow) is not cleared by the liver and is instead pumped back into the circulation resulting in what is known as a 'jaundiced appearance' (typically yellowish pigmentation of the skin and eyes). Jaundice was a sign of the liver's response to injury. Cachexia (wasting) occurred: in advanced liver disease the body starts to use its own store of fat and muscle as a source of energy rather than food and muscle bulk is lost. Mr Laing lost all fat and looked thin, a feature of very late disease. Portal hypertensive gastropathy occurred. Blood normally travels from the gut into the liver, a soft organ, under low pressure. If the liver becomes distorted and scarred it is hard for the blood to get from the gut into the liver. It starts to go backwards and seek other routes. The stomach, downstream of the pressure effect, becomes very distended, thickened with blood. The gut comes under high pressure and that makes it develop varices (varicose veins) which can bleed.<sup>497</sup>

**7.265** Dr Alexander said that understanding of the natural history of Hepatitis C in older patients is no longer as it was initially thought. As now understood, an individual infected with Hepatitis C at nearly 67, as Mr Laing was, was likely to experience relatively rapid progression of disease. Most early experience was based on non-A, non-B Hepatitis (NANB Hepatitis) transfusion-related liver disease prior to the introduction of Hepatitis C testing. In those circumstances the majority of people died of diseases related to the reason for which they had been transfused, not to the hepatitis that arose as a result. As a result, there was an artificially skewed view of what NANB Hepatitis/Hepatitis C did to patients. It was not until the introduction of testing for Hepatitis C in 1991 that it was realised that many people had very different disease outcomes from that which had been previously described. The real picture was described about five or six years later.<sup>498</sup>

---

<sup>490</sup> Day 4, pages 29–30

<sup>491</sup> Letter from ARI to GP dated 12 September 2003 [LAI.001.0031]

<sup>492</sup> 'Decompensation' is the failing condition of an organ, such as the liver.

<sup>493</sup> Dr Alexander – Day 4, page 31

<sup>496</sup> Day 4, pages 32–33

<sup>497</sup> Day 4, pages 34–35

<sup>498</sup> Ibid pages 36–37

**7.266** Dr Alexander had extensive research experience. His laboratory's work on the effect of ageing (measuring people's 'biological age') and outcome is discussed in Chapter 16, *Knowledge of Viral Hepatitis 3 – 1986 Onwards*, at paragraph 16.65. In short, physical changes in the structure of DNA as people grow older makes the DNA vulnerable to damage. The same mechanism affects Hepatitis C–positive patients, once they reach a certain biological age. If the patient does not have an effective immune system, they cannot cope with Hepatitis C so that the virus takes a stronger grip.<sup>499</sup> The immune system begins to be impaired generally when one gets to around 60; in an HCV- positive patient that process is accelerated and response to treatment is also affected. Dr Alexander's laboratory found that the biological age at which treatment was significantly less likely to be effective – the treatment cut-off age – was 58. Mr Laing's age is a particular indication that he would not have benefited from antiviral treatment.<sup>500</sup>

### Source of infection

**7.267** As discussed in paragraphs 7.235 and 7.240, it was clearly established that Mr Laing contracted Hepatitis C from the blood transfusion received at the time of his surgery for cancer in 1990. He died of the complications of that infection. At the time of his surgery in 1990, donated blood was not screened in the UK for Hepatitis C: screening was introduced in 1991. There was an issue for the Inquiry whether, had HCV screening been in place in Scotland, the donation that infected Mr Laing would have been identified and not used.

**7.268** After HCV was identified in 1988, its genetic characteristics became the subject of intense research.<sup>501</sup> Variations in those characteristics were identified which were sufficient to define genetic sub-groups, or 'genotypes', which differ from others of the same virus, although not sufficiently to be considered different viruses. The genes of individual genotypes, like other organisms in the body, define their 'genomes'. The immune system responds to the activity of a virus by producing antibodies, proteins that seek to neutralise part of the virus. Antibodies remain in the body and, with appropriate technology, can often be identified. With modern, sophisticated technology, the genotype of the virus can be determined by scanning for particular antibodies to the virus.<sup>502</sup>

**7.269** At the date of Mr Laing's surgery in 1990, early tests had been devised for screening donors' blood for HCV. The tests, known as enzyme-linked immunoabsorbent assays (ELISAs), were chemical products developed by pharmaceutical companies from components that would react with antibodies to HCV if they were present in a sample of serum, producing a change of colour.<sup>503</sup> More sensitive second-generation ELISA tests were used in screening blood donors from autumn 1991.

**7.270** First-generation ELISAs targeted two specific areas of HCV that, as events were to prove, were characteristic of Genotype 1, which was particularly prevalent in the USA but were not present, so far as is material for present purposes, in Genotype 3 of the virus.<sup>504</sup> Technically, the first-generation tests were directed against the NS4 region of the virus, a non-structural region of the virus found in Genotype 1. So the components used for

---

<sup>499</sup> Ibid pages 42–44 and 46–47

<sup>500</sup> Ibid pages 42–44 and 46–47

<sup>501</sup> See Chapter 13, *Knowledge of Viral Hepatitis Now* and Chapter 16, *Knowledge of Viral Hepatitis 3 – 1986 Onwards*

<sup>502</sup> Dr Dow – Day 4, pages 54–61

<sup>503</sup> Ibid pages 85–86

<sup>504</sup> Ibid pages 62–64

first-generation tests could detect only Genotype 1 efficiently. They did not detect many Genotype 2 or 3 cases at all well.<sup>505</sup>

**7.271** In the result, the first-generation tests initially introduced for Hepatitis C screening of blood donations appeared relatively successful in identifying Hepatitis C-positive material in the USA but relatively unsuccessful in the UK where there was a high prevalence of Genotype 3 HCV.

**7.272** It became of interest to identify the HCV genotype of the donor whose blood was transfused to Mr Laing. This was in order to determine whether the infection might have been detected and the donation deferred – that is withdrawn from use for transfusion – if routine screening of blood donations had been carried out at the time of Mr Laing's transfusion in August 1990.

**7.273** The infected donation was traced through the national look-back process, as already noted. The donor had a blood transfusion in the 1960s or 1970s and may have acquired infection at that time, which was long before issues of testing for Hepatitis C became relevant.<sup>506</sup> A retained serum sample was found to be Hepatitis C-positive, using a second-generation ELISA test, on 8 January 1992. Research identified the genotype of the virus in question as Genotype 3.<sup>507</sup> Specifically, the donor genotype had high concentrations of four positive antibodies involved in the fight against Hepatitis C. Components of the second-generation tests targeted specific parts of the virus genome (components C22 and C33) found in Genotype 3.

**7.274** In March 1992, as part of a research project in which Dr Brian Dow<sup>508</sup> was involved, the same sample of the donation was re-tested using the Abbott first-generation test which had been available at the time of the original donation in some Scottish virology laboratories. The sample tested negative for Hepatitis C.<sup>509</sup> If the donation had been tested at the time it was given and transfused to Mr Laing, the first-generation tests then available would have been negative. The blood would have been banked and used for clinical purposes, as it was in the event in the course of Mr Laing's surgery.<sup>510</sup>

### Surrogate testing

**7.275** Before the introduction of the first-generation ELISAs, blood could be screened using tests which were not directly related to Hepatitis C itself but used assays that might give an indication that the subject may have been infected with Hepatitis C. These are known as 'surrogate' tests.<sup>511</sup> They were not conclusive on the presence of HCV or its antibody but indicated signs associated with infection. Observation had shown that in patients who had Hepatitis C there was a high correlation with raised levels of alanine amino transferase (ALT), a liver enzyme. One surrogate test therefore targeted ALT levels. There was also a reasonable correlation between having Hepatitis C and also having the

---

<sup>505</sup> Ibid pages 58–59

<sup>506</sup> Ibid page 78

<sup>507</sup> Ibid page 53; Dr Dow's amended report [PEN.012.0344]

<sup>508</sup> Now retired, Dr Dow was Consultant Clinical Microbiologist of the SNBTS Microbiology Unit, Glasgow. In 1992, he was Principal Clinical Scientist of the Microbiology Unit.

<sup>509</sup> Dr Dow – Day 4, page 65; The research project was reported in 1993: McOmish et al, 'Detection of three types of hepatitis C virus in blood donors', *Transfusion*, 1993; 33, [PEN.001.0018]

<sup>510</sup> Dr Dow – Day 4, page 65

<sup>511</sup> A surrogate marker is a directly measurable physical entity (usually measured in a blood test) that correlates (has a statistical association) with a disease where it is not possible to test directly for the disease or where any direct test would be problematic. See Chapter 27, *Surrogate Testing of Donated Blood for non-A, non-B Hepatitis* for more detailed discussion.

antibody to Hepatitis B core antigen (anti-HBc).<sup>512</sup> The other surrogate test accordingly targeted anti-HBc.

**7.276** Within the same research project in 1992 referred to in paragraph 7.274 above, Dr Dow and his colleagues therefore looked at surrogate testing. They carried out anti-HBc testing and found that the sample from the donor involved in Mr Laing's case was one of those which was anti-HBc negative. Dr Dow concluded that the result would have been the same had the donation been tested at the time of donation.<sup>513</sup> Dr Dow's research project had investigated the ALT levels in 90 donations but the donation in question was not among those investigated for ALT.<sup>514</sup> Subsequently, however, Dr John Gillon, SNBTS, was able to access and follow up the records of the donor whose blood was implicated in Mr Laing's infection with Hepatitis C. The records showed that the donor's ALT level was tested on four occasions, in February and August 1992, in December 1993 and in October 1994. On each occasion the level was well within normal limits. Dr Dow concluded that it was likely that the implicated donation would have given a normal ALT value if the donor's blood had been tested in August 1990.<sup>515</sup>

**7.277** The question whether ALT surrogate testing should have been introduced in Scotland in the period before introduction of the anti-HCV assay was extensively debated and is discussed at length in Chapter 27, *Surrogate Testing of Donated Blood for non-A, non-B Hepatitis*. In the circumstances, however, ALT testing of the donated blood would not have produced counter-indications to the use of the donation in Mr Laing's case.

**7.278** It was submitted that Mr Laing's case raised systemic issues related to the use of blood from people who had received transfusions; about the non-introduction of surrogate testing in Scotland; and about the screening of donations.<sup>516</sup> There is no basis for the view that, given what was known in 1990, donors who had themselves received a donation should have been excluded from donating at that time. There are systemic issues for the Inquiry relating to the non-introduction of surrogate testing. However, the decisions, and the failures to reach decisions, that had the result that surrogate testing was not adopted in Scotland, could not have influenced Mr Laing's case. All of these issues are dealt with in Chapter 27, *Surrogate Testing of Donated Blood for non-A, non-B Hepatitis*. Similarly, had screening of blood donations been in place in the summer of 1990, the kits used would have been first-generation ELISAs and would not have detected Hepatitis C in the donation which subsequently infected Mr Laing. Mr Laing's death from complications of his infection with Hepatitis C, having survived serious and potentially fatal cancer, was a personal tragedy for Mrs Laing and her family. That is the light in which it should continue to be seen.

### **Mr Laing's treatment as a patient**

**7.279** Dr Alexander considered that Mr Laing's treatment had been exemplary.<sup>517</sup> In this case, the summary of his views in his report is the best expression of the position:

The short interval of just six years between acquisition of hepatitis C virus infection and documentation of cirrhosis at liver biopsy and the seven years

---

<sup>512</sup> Dr Dow – Day 4, pages 67–68

<sup>513</sup> Dr Dow – Day 4, pages 70–71; Dr Dow's amended report [PEN.012.0344] at 0345

<sup>514</sup> Ibid page 70

<sup>515</sup> Dr Dow's amended report [PEN.012.0344] at 0345

<sup>516</sup> Closing Submission [PEN.019.0777]

<sup>517</sup> Day 4, page 42

that followed thereafter to his death, are consistent with what we now know about the natural history of hepatitis C virus infection. The proportion of patients that go on to develop cirrhosis and the rate at which cirrhosis develops subsequently are greatly accelerated in the elderly and in particular in men over 60. The fact that he had been overweight earlier in life may have been an additional confounding factor increasing his chance of becoming cirrhotic and increasing the rate at which the disease would progress. The first large publications drawing attention to the importance of age on the progression of liver fibrosis were published around 1997 and would have been discussed in abstract form, probably in the preceding few months. Thus the information that was provided to Mr Laing at the time of his biopsy in 1996 was probably 'best known practice'.

The fact that he was told that his disease was benign and was likely to remain so may well have influenced his decision not to accept the offer of anti viral therapy and it seems clear to me from the letters around that time that he was likely to have been told that the Interferon- $\alpha$  treatment was not likely to offer him a cure. I agree that was certainly true at the time and the response rate to treatment with Interferon- $\alpha$  in our centre was just 9% of cases ... with an even lower rate in the elderly and those with cirrhosis.

I do think, however, that the biopsy ... is likely to have been under reported in terms of the stage of fibrosis and that the possibility that the biopsy might have represented a higher stage of fibrosis was not appreciated by the clinicians. A fragmented biopsy, such as that in this case, is not one on which to base a prognosis with confidence.

It must be noted that Mr Laing survived 13 years after his diagnosis of carcinoma of the rectum with Duke's C histology, which is an astonishing outcome. I do not feel that even if there had been a better indication of his fibrosis stage in 1996 that it would have been possible to modify the natural history of his hepatitis C virus infection as the treatment available at that time was relatively ineffective and more so in elderly males with cirrhosis. If he had presented now with Pegylated Interferon and Ribavirin available the chances are that he would not have responded to treatment and if I was asked now to consider treatment I would very likely not offer him treatment with Pegylated Interferon and Ribavirin, the best available current therapy, because of his age and cirrhosis and the low probability of a response.<sup>518</sup>

**7.280** It is a matter of agreement on the part of Mrs Laing and the other 'patient interest' core participants that there appear to have been no reasonable precautions whereby Mr Laing's death might have been avoided once he had contracted Hepatitis C.<sup>519</sup>

## Conclusions

**7.281** Factors contributing to the death of Mr Laing were:

- (i) Mr Laing died from Hepatitis C-related liver disease.

---

<sup>518</sup> Report on Alexander Black Laing [LAI.001.1125] at 1127–1128

<sup>519</sup> Closing Submission [PEN.019.0777]

**7.282** Infection with Hepatitis C:

- (ii) Mr Laing was infected with Hepatitis C as a result of transmission of blood at the time of his surgery for Duke's C carcinoma on 7 August 1990.
- (iii) The surgery saved his life. It was never suggested that surgery could have been carried out without transfusion.
- (iv) The donor's infection was discovered in the course of the UK national look-back programme for transfusion-related Hepatitis C in 1995 and the blood used in Mr Laing's operation was traced to the infected donation in the follow-up stages of that investigation.
- (v) The donor's infection probably resulted from the transfusion of an infected donation in the 1970s. In 1990, there was no requirement for a policy of excluding recipients of previous blood donations from themselves donating blood.
- (vi) In 1990, anti-Hepatitis C testing was in its infancy and had not been adopted to screen blood donations in the UK.
- (vii) If the first-generation ELISA tests that were available at the time in 1990 had been used, the donor's Hepatitis C would not have been discovered.
- (viii) Surrogate testing for anti-HBc was not in use but, if it had been, it would not have given rise to an inference of possible Hepatitis C: the infected donation, when retrospectively tested, was negative for anti-HBc.
- (ix) Surrogate testing using ALT levels was not in use, but if it had been it would not have given rise to an inference of possible Hepatitis C: the donor had normal levels of ALT on two occasions in 1992, once in 1993 and once in 1994.

**7.283** Progression of disease:

- (x) Mr Laing's Hepatitis C progressed as would have been predicted by current understanding of the disease in a man of his age.

**7.284** Mr Laing's management as a patient:

- (xi) Mr Laing's management as a patient was an illustration of exemplary care.

## **Victor Tamburrini**

### **Introduction**

**7.285** Mr Victor Tamburrini was born on 27 April 1957. He died at the Royal Infirmary of Edinburgh on 17 November 2004, aged 47 years. The certified causes of death were liver transplant graft failure and recurrent Hepatitis C.<sup>520</sup>

### *The recovery of Mr Tamburrini's health records*

**7.286** Health records for Mr Tamburrini were recovered from the Glasgow Royal Infirmary (GRI), the Greater Glasgow and Clyde Community Alcohol Service and the Royal Infirmary of Edinburgh (RIE). In addition, relevant transfusion related records were obtained from the SNBTS. The Inquiry was unable to recover the full GP records of Mr Tamburrini.

**7.287** Mr Tamburrini's GP records were obtained by the Crown Office and Procurator Fiscal Service (COPFS) in January 2007 following a request by Messrs Thompsons, solicitors, on

---

<sup>520</sup> Death certificate [TAM.001.2946]

behalf of Mrs Tamburrini, to Strathclyde Police, for sight of the records.<sup>521</sup> Mrs Tamburrini was pressing for a Fatal Accident Inquiry (FAI) in to her husband's death. While Mr Tamburrini's other health records continued to be held by the COPFS, from which they were recovered by the Inquiry, the GP records had been returned to the NHS National Services Scotland Practitioner Services. It is likely that they were returned in 2007.<sup>522</sup> That department destroyed the original GP records on 16 June 2009.<sup>523</sup>

### *The destruction of Mr Tamburrini's original GP records*

**7.288** In ordinary course, destruction of medical records conforms to the 'Guidance for the Retention and Destruction of Health Records' issued by the former Scottish Office in 1993. In the case of GP records, the guidance recommends a retention period of three years after a patient's death.<sup>524</sup> If the guidance had been followed, Mr Tamburrini's GP records would have been destroyed on receipt by Practitioner Services or shortly thereafter: the three-year retention period had long expired.

**7.289** In January 2009 Crown Counsel instructed that there should be no FAI into Mr Tamburrini's death.<sup>525</sup> However, Scottish Ministers continued to consider referring Mr Tamburrini's death to this Inquiry and that was done on 13 November 2009. Destruction of the GP records therefore occurred while consideration was still being given to the reference of Mr Tamburrini's death to the Inquiry.

**7.290** How that came about is unclear. The GP records appear to have been returned to Practitioner Services<sup>526</sup> before the decision to instruct no proceedings in relation to an FAI and there has been no explanation why the COPFS took that step while retaining other medical records. So long as a decision on an FAI remained to be reached, the GP records were potentially required as evidence and the COPFS should have been aware of that possibility. At the time the COPFS was not aware of the Scottish Government Health Directorate document retention policy.<sup>527</sup> However, it is clear that the records remained available in the hands of Practitioner Services after the decision by the COPFS on FAI proceedings.

**7.291** The destruction of the records by Practitioner Services remains unexplained. However, at the time of their destruction a summary of the GP records was prepared.<sup>528</sup> In addition, the hospital records include correspondence with Mr Tamburrini's GP. The Inquiry is satisfied that the records produced to it were sufficient to enable the investigation of his death. The lack of the original GP records did not inhibit the investigation.

### **Initial symptoms and diagnosis of Hepatitis C Virus infection**

**7.292** How and when Mr Tamburrini acquired infection with Hepatitis C is not known. Mr Tamburrini married for the second time on 8 March 1991. His widow, Mrs Jean Tamburrini, had limited information about his medical history before they met in 1987. She knew that he had been in a car accident and had suffered serious burns in September

<sup>527</sup> Ibid [PEN.001.0303]

<sup>528</sup> Summary of records [TAM.001.1459]

1984. In general, however, her evidence related to the period from 1987 onwards. In the circumstances she was unable to provide an insight into possible dates of infection before 1987.

**7.293** Mr Tamburrini was diagnosed with Hepatitis C in September 2001.<sup>529</sup> By then he had signs and symptoms strongly suggestive of severe liver damage. That would provide the latest date by reference to which estimates of the duration of infection might be made on the basis of knowledge of the natural history of the disease. There was, however, evidence that, in retrospect, indicated he was developing liver disease at an earlier period.

### *Early signs and symptoms*

**7.294** At Christmas 1991, Mr Tamburrini felt unwell and could not stop falling asleep. He was doing heavy work at a fruit market as a porter or deliveryman, however, and the possible significance of his condition only became apparent later.<sup>530</sup>

**7.295** In about 1994 or 1995 he worked for his uncle in a factory for around 10 months. The work was hard and physical and he had difficulty in maintaining the energy levels required and had to leave the job. He then began working in licensed premises owned by his brother-in-law, first as a barman and then, from about 1997, as bar manager. He suffered from lethargy and slept a lot but his employer was supportive and accommodated him.<sup>531</sup>

**7.296** In 1998, Mr Tamburrini was feeling unwell: he had suddenly begun to put on weight, experienced heartburn and had poor appetite. His ankles and abdomen were swollen and he was increasingly lethargic.<sup>532</sup> In May 1998, he went to see his GP complaining of a painless swelling in his right breast.<sup>533</sup> It was recorded that there had been no trauma or serious illness in his recent medical history. He was referred to the GRI where he was seen at the professorial breast clinic. In the referral form, the GP noted that Mr Tamburrini had mentioned a habit of consuming large quantities of alcohol. The hospital report to the GP following examination on 15 July noted that Mr Tamburrini had a history of alcohol abuse. Atypical gynaecomastia (benign enlargement of breast tissue in males) was diagnosed in the right breast and it was proposed that the affected area should be removed. The left breast did not present with similar swelling.<sup>534</sup> On admission on 10 December 1998, it was found that the lump in the right breast which had been noticed first was not palpable and that a lump had developed in the left breast. On the following day bilateral subcutaneous mastectomy was carried out.<sup>535</sup> Mr Tamburrini was discharged from hospital on 15 December 1998 with a note stating that he was well and was to be followed up in clinic.<sup>536</sup>

**7.297** Gynaecomastia can be observed in men with advanced liver disease from any cause. Not infrequently it is also seen, in the absence of cirrhosis, in men who are putting on weight, as Mr Tamburrini was, and in heavy drinkers.

<sup>529</sup> See paragraph 7.302

<sup>530</sup> Witness Statement of Mrs Jean Tamburrini [PEN.001.0309]

<sup>531</sup> Ibid [PEN.001.0309] at 0310; Affidavit of Bernard Fisher [PEN.018.1559]; Mrs Jean Tamburrini – Day 1, pages 14-15

<sup>532</sup> Witness Statement of Mrs Jean Tamburrini [PEN.001.0309] at 0310

<sup>533</sup> GP's request to the GRI for out-patient consultation dated 2 June 1998 [TAM.001.2583]

<sup>534</sup> Letter from the GRI to GP dated 17 July 1998 [TAM.001.2582]

<sup>535</sup> GRI careplan [TAM.001.2907]

<sup>536</sup> Letter from the GRI to GP dated 20 January 1999 [TAM.001.2574]

**7.298** On 27 January 1999, Mr Tamburrini was admitted to the Lister Department of Surgery, at the GRI, as an emergency patient, complaining of severe epigastric (abdominal) pain. He gave a history of diarrhoea about a week earlier. His pain had gradually increased and on admission he had mildly raised serum amylase (an enzyme produced by the pancreas) but no other indicators of severe disease. An ultrasound scan disclosed some large stones in his gallbladder. There was a diagnosis of '(?)Viral induced acute pancreatitis'. He was discharged well, to be followed up in the clinic.<sup>537</sup> He was reviewed on 24 February 1999, found to be well and discharged without further follow-up.<sup>538</sup>

### *Towards a diagnosis of liver disease*

**7.299** In 2000, Mr Tamburrini again began to put on weight around his abdomen, gave up exercise because he could not manage it and, on holiday, was depressed and grumpy. He had swollen ankles and could not wear normal shoes.<sup>539</sup> In 2001, the Department of Oral Medicine at the Glasgow Dental Hospital and his GP each separately referred him to the GRI for examination. The Department of Oral Medicine referred him specifically to the Haematology Department and he was seen at Dr Isobel Walker's clinic. The GP's referral letter reported a history of previous admissions and findings and described the basis of the current referral as 'recently developed moderate/severe oedema of both legs', the abnormal accumulation of fluid, clinically apparent as swelling. It reported that Mr Tamburrini's liver function tests were deranged and provided recent values. The referral letter from the Department of Oral Medicine noted 'peri-orbital oedema [swelling around the eyes] and bilateral ankle swelling' in addition to the oral problems for which he had been examined.<sup>540</sup>

**7.300** Dr Lorna McLintock of the Department of Haematology reported to the Dental Hospital on 8 August 2001.<sup>541</sup> She noted that the abnormal blood parameters included elevated mean corpuscular volume (MCV), thrombocytopenia, mild eosinophilia and mild reticulocytosis.<sup>542</sup> She thought that Mr Tamburrini's blood parameters all related to liver disease but wished further tests to be carried out. Dr David Mutimer, a Consultant Hepatologist who provided expert testimony to the Inquiry, said that the features reported by Dr McLintock were all seen in patients with advanced liver disease, which was therefore indicated at that time.<sup>543</sup> MCV is a measure of the size of the red blood cells and a high MCV is found typically in patients with cirrhosis, particularly when due to alcohol.<sup>544</sup> Thrombocytopenia (a decrease in the level of platelets in the blood), eosinophilia (a decrease in another blood component, eosinophii) and reticulocytosis (an increase in immature red blood cells) are also seen in patients with cirrhosis or advanced liver disease.<sup>545</sup>

**7.301** Mr Tamburrini was reviewed by Dr McLintock on 5 September 2001.<sup>546</sup> She again found his liver function test results to be elevated. She reported to his GP that Mr Tamburrini 'obviously' had significant liver disease. She sent blood for autoantibody serology and hepatitis serology.

### *Diagnosis with Hepatitis C*

**7.302** A Hepatitis C test, using polymerase chain reaction (PCR) technology, proved positive<sup>547</sup> and on 26 September 2001 Mr Tamburrini was told that he had contracted Hepatitis C.<sup>548</sup> Mrs Tamburrini was also tested for the presence of the Hepatitis C virus (HCV): she was not infected.<sup>549</sup> Dr McLintock noted that Mr Tamburrini did not feel that he had a history of any high-risk behaviour associated with the transmission of Hepatitis C.<sup>550</sup> Blood tests performed at that time strongly suggested severe liver damage: the results were consistent with cirrhosis and hepatic decompensation. The MCV score was again very high at 111.<sup>551</sup> Dr Mutimer thought that the blood test results would be consistent with cirrhosis and hepatic decompensation due to the effect of alcohol, to Hepatitis C or to a combination of the two.<sup>552</sup> Mr Tamburrini thereafter attended Dr AJ Stanley's Liver Clinic at the GRI before being referred to the Liver Transplant Unit (LTU) at the RIE in February 2002.<sup>553</sup> Mr and Mrs Tamburrini began to understand that the condition was serious.

### **Possible cause of HCV infection**

**7.303** There are two main groups of causes of HCV infection. The first group comprises transmission of infection during health care, by transfusion of infected blood, blood components or blood products, or hospital-acquired transmission, for example by needle-stick injury. The second group comprises causes of infection outwith a healthcare setting. Overwhelmingly the commonest cause of infection in the second group, in Scotland, has been intravenous drug use and sharing HCV-infected materials. More rarely, HCV may have been acquired from contaminated tattooing or body piercing equipment. These possibilities will be explored in light of the fact that Mr Tamburrini already had cirrhosis at the latest in 2001 when he was aged 44.

**7.304** Mr Tamburrini's medical records were examined to ascertain whether there was evidence of medical procedures that might have involved blood transfusion and created a risk of transmitting infection. The records were examined specifically in an attempt to identify a date of transmission. The examination was not limited to the period within which he might be thought to have acquired infection.

### *Possibility of infection during an appendicectomy in December 1968*

**7.305** Mr Tamburrini had an appendicectomy as a child, in 1968.<sup>554</sup> That was the first occasion on which he might have had a blood transfusion. The appendicectomy was noted elsewhere in his medical records.<sup>555</sup> There was no reference to transfusion or to any event of an exceptional nature at the time of the operation that might have indicated a need for transfusion. The appendicectomy scar, in itself unremarkable, was noted throughout the records without comment.

<sup>554</sup> Summary of GP records printed on 6 January 2005 [TAM.001.1459] at 1460

<sup>555</sup> eg GRI careplan dated 10 December 1998 [TAM.001.2907]

**7.306** Professor Willem van Aken was asked to express an opinion on the likelihood of transfusion at the time of the procedure. Professor van Aken was, until retirement, Director of the Board of the Central Laboratory of the Netherlands Red Cross Blood Transfusion Service and had a long and distinguished record in that service. He was well qualified to comment on the use of blood transfusion for surgical procedures at the relevant period. In his view it would have been a rarity for anyone ever to have received a transfusion of blood in the course of an appendicectomy in 1968. It would happen only very seldom and only when there was a complication and major bleeding. Most appendicectomy procedures would not have required the transfusion of blood.<sup>556</sup>

**7.307** As a medical scientist, Professor van Aken could not rule out the possibility that there had been a blood transfusion. On the evidence as a whole, however, there is no basis for a finding that Mr Tamburrini did have a blood transfusion in 1968. The records do not disclose any complication or major bleeding. Bare possibility could not support a finding that there was a transfusion in the face of Professor van Aken's evidence.<sup>557</sup>

**7.308** On a balance of probabilities, Mr Tamburrini was not transfused at the time of his appendicectomy and that procedure cannot have been the occasion of transmission of infection.

#### *Possibility of infection during treatment for burns in 1984*

**7.309** On 7 September 1984, Mr Tamburrini was admitted to the burns unit of the GRI having sustained extensive surface area burns as a result of a vehicle fire: the accident Mrs Tamburrini knew about. He was transfused with six units of Plasma Protein Solution (otherwise Stable Plasma Protein Solution, SPPS), an albumin preparation, each recorded as having come from a specific batch of product numbered 1194 released by the SNBTS on 10 August 1983.<sup>558</sup> Transfusion of SPPS was a standard procedure in the circumstances, in this application much safer than plasma or whole blood.<sup>559</sup> Severe burns involve the loss of fluid from the circulation: in the vicinity of the burn, blood vessels become dilated and leak protein-rich fluid, creating a risk of shock. Blood pressure drops and there tends to be an urgent need to restore blood volume and to increase osmotic/oncotic pressure, which is a composite of the protein content in the blood and the resistance provided by tissue. In some patients the albumin level in the blood drops. SPPS specifically restores albumin as part of the process of increasing the volume of circulating blood. Mr Tamburrini recovered, and was discharged on 6 October 1984.<sup>560</sup>

**7.310** The transfusion of SPPS was the second event that provided a focus for investigation as a possible source of transmission of HCV infection. In the UK, and in Scotland in particular, SPPS was prepared at the material time in accordance with requirements set out in a monograph contained in the British Pharmacopoeia (BP) issued in 1980.<sup>561</sup> The batch from which the SPPS administered to Mr Tamburrini was drawn was prepared in that way.<sup>562</sup> The critical, penultimate stage in the process was described in the monograph:

<sup>559</sup> Professor van Aken – Day 2, pages 20–22

<sup>560</sup> Letter from the GRI to GP dated 10 October 1984 [TAM.001.2591]

<sup>561</sup> Excerpt from the BP (referred to as Plasma Protein Fraction) [PEN.001.0259]; Statement of Drs Perry and Cuthbertson on SPPS Batch No 1194 dated 4 March 2011 [PEN.011.0048] at 0049

<sup>562</sup> Dr Cuthbertson – Day 1, page 123 et seq

The albumin fraction, prepared by a suitable fractionation technique, is dissolved in water .... The solution is sterilised by *Filtration*, distributed aseptically in sterile containers, and sealed so as to exclude micro-organisms. It is then heated to, and maintained for ten hours at, 59.5° to 60.5° so as to prevent the transmission of hepatitis.<sup>563</sup>

**7.311** The records relating to the batch were comprehensive.<sup>564</sup> The product in question was pasteurised at 60°C for 10 hours.<sup>565</sup>

**7.312** The production process was described in detail by Dr Bruce Cuthbertson, currently Quality Director of the SNBTS.<sup>566</sup> 'Albumin' is the term used to describe a product that contains in excess of 95% albumin protein. SPPS must contain in excess of 90% albumin protein.<sup>567</sup> There is a 'purity' distinction between the products but there is no difference in terms of risk of transmission of hepatitis viruses. Both products are pasteurised by heating at 59.5°C to 60.5°C for 10 hours.<sup>568</sup>

**7.313** Albumin has had an almost unblemished record of safety in clinical use since its introduction in 1940 by the US Army for the battlefield treatment of trauma.<sup>569</sup> Albumin products have only twice been reported to transmit hepatitis: the first time in an experiment carried out on human volunteers in the 1940s when pasteurised and unpasteurised albumin doses were administered (those who received unpasteurised doses were infected with Hepatitis B while those who received the pasteurised product were not);<sup>570</sup> the second time, which again involved transmission of Hepatitis B, in 1973.<sup>571</sup> After full investigation it was shown that, in that instance, the pasteurisation process was defective. Pasteurisation was carried out in a bulk tank, after which the preparation was decanted into containers. The structure of the bulk-pasteurisation tank allowed for pockets of material to remain inadequately mixed with the remaining material and thus to fail to be subject to the complete heating cycle.<sup>572</sup> Professor van Aken gave further details of the 1973 incident.<sup>573</sup> Albumin has never been reported to transmit Hepatitis C.<sup>574</sup>

**7.314** The BP stipulation for pasteurisation in the final container addressed the risk illustrated by the 1973 incident.<sup>575</sup> The process requirements ensured that after sealing there was no prospect of there being incomplete pasteurisation or of the product being re-contaminated.<sup>576</sup>

**7.315** Professor van Aken was asked to comment on whether the word 'prevent' was apposite in the sentence from the BP: 'It is then heated to, and maintained for 10 hours at 59.5°C to 60.5°C so as to prevent the transmission of Hepatitis'. He had no doubt or uncertainty about the use of the word 'prevent' in this context.<sup>577</sup>

<sup>576</sup> Dr Cuthbertson – Day 1, page 133

<sup>577</sup> Professor van Aken – Day 2, pages 27–28; Excerpt from the BP [PEN.001.0259]

**7.316** Dr Cuthbertson explained that pasteurisation was the end stage in the production process.<sup>578</sup> Fractionation of plasma extracted various proteins using a variety of biochemical techniques, principally cold ethanol fractionation. The SPPS produced was sterile-filtered to remove bacteria and was then dispensed into bottles in an aseptic filling suite. The bottles and stoppers had already been sterilised separately at 121°C for 15 minutes and held in sterile conditions until used. Four hundred millilitres of liquid were placed in each bottle, the stopper was inserted and an aluminium overcap was put on top. The caps were then sealed. The bottles were crated, reserving two for quality control. The crated bottles proceeded to pasteurisation in a chamber commissioned and developed by the Protein Fractionation Centre (PFC, the manufacturer of blood products in Scotland). The bottles were sprayed with hot water for pre-wash, to remove any protein that might have been deposited on their exterior surfaces in the course of filling or handling. Thereafter the bottles were rapidly heated to 60°C for 10 hours.<sup>579</sup>

**7.317** Professor van Aken commented generally on the process of fractionation and in particular on the distribution of virus particles over the range of products.<sup>580</sup> It had been shown that the distribution was uneven, with some fractions containing more contamination than others.<sup>581</sup> Albumin was produced from a fraction that had been found to contain only a minute quantity of Hepatitis C virus after the fractionation process.<sup>582</sup> The major contributor to viral inactivation, however, was the pasteurisation process which followed fractionation. The position relative to the pasteurisation step was summed up by Brian Erstad and others in an article for the journal *Pharmacotherapy*:

Both HSA [human serum albumin] and PPF are manufactured with pasteurization procedures that have led to an excellent viral safety record based on 50 years of clinical use .... The pasteurization process is effective in eradicating known viral pathogens when good manufacturing practices are followed.<sup>583</sup>

**7.318** Professor van Aken's report stated that published studies had shown that heating of albumin for only 10 minutes at 60°C results in levels of virus inactivation and reduction, recognised as providing a very high margin of safety. He pointed out that the pasteurisation of albumin for 10 hours at 60° C is 60 times longer than is needed to inactivate hepatitis viruses.<sup>584</sup>

**7.319** He added in oral evidence:

The WHO [World Health Organization] expert committee on plasma products ... has addressed this issue in a very extensive report in which all these papers here are included, and one of the conclusions is in fact that ten minutes at 60 degrees Celsius results in a virus reduction of more than 16 logs, which means that ... it is about a risk of one in 16 millions that still a virus is not inactivated. So it goes well beyond our imagination that there is still some virus left after that period of time.<sup>585</sup>

<sup>585</sup> Day 2, pages 44–45; Professor van Aken's report [PEN.001.0306] at 0308

**7.320** The original batch records for batch 1194, from which the SPPS used to treat Mr Tamburrini came, were examined to ascertain the procedure in the particular case. They showed that the pasteurisation cabinet was checked and found to be operating satisfactorily. The loading of the crates was recorded. The temperature was monitored by a Honeywell probe placed in a representative bottle in each crate of 10 bottles. The run was timed and the temperature maintained throughout was recorded as 60°C. The procedure was recorded in detail and explained in oral testimony by Dr Cuthbertson.<sup>586</sup> He noted that this was before the digital age: the data were recorded on charts. There was an independent check that the probes were in fact reading at 60°C. The procedure confirmed that the bottles were all behaving consistently.<sup>587</sup>

**7.321** The completed bottles were placed in cages, security-sealed, labelled with the individual batch number and placed in incubation for two weeks at about 30°C. Albumin is a good medium for bacterial contamination<sup>588</sup> and this procedure allowed any bacterial contamination that might be present to grow and become evident. Dr Cuthbertson had signed off the microbiology test results at the time.<sup>589</sup> It was only after quality control on a sample of pasteurised bottles, which included demonstration that the product had been effectively pasteurised, that the product was released for inspection.<sup>590</sup> The caps were inspected to ensure their integrity and the bottles were inspected under direct light and polarised light to look for the presence of visible contamination. Pasteurisation changes the characteristics of albumin from clear to opalescent. Rejection was a common occurrence. From the specific batch in question, 110 bottles were rejected. Most of these will have been because of the presence of fibres in the bottle. Once all the bottles had been inspected they were released for labelling and packing (or discarded had they failed the inspection).<sup>591</sup>

**7.322** Professor van Aken carried out an independent review of the records relating to the particular batch.<sup>592</sup> The procedures followed the guidance to pasteurise in the final individual containers as set out in the BP and in WHO guidelines.<sup>593</sup> His conclusions were:

The batch of SPPS administered to Mr Tamburrini was manufactured using methods which were at the time (and still are) widely recognised as being capable of eliminating any risk of virus transmission.

The records of batch number 1194 indicate that its manufacture, and in particular its pasteurisation, was carried out according to recognised industry and pharmacopoeial standards.

The answer to the query therefore is that the transmission of hepatitis C by SPPS is most unlikely ....<sup>594</sup>

<sup>594</sup> Professor van Aken's report [PEN.001.0306] at 0308

**7.323** He was asked why he did not say 'impossible' and added in oral evidence:

Well, 'impossible' is a word which I use only very rarely because I have learned through my career that some events you can judge to be highly unlikely or even further, but you have to be cautious, so I cannot oversee the whole chain of events which was related to this incident because it is a chain of events; it doesn't stop with the manufacturing. It is also what happened during the administration, what happened in the hospital, which I cannot oversee, which I have no reports about, which I have no data about. So that's why I thought it would be more accurate to say "highly unlikely".<sup>595</sup>

**7.324** Absolute proposition, positive or negative, has to be avoided generally in scientific analysis.<sup>596</sup>

**7.325** Reviewing the medical history, Dr Mutimer agreed with the view that it was extremely unlikely that Hepatitis C was acquired as a consequence of administration of that plasma.<sup>597</sup>

### *Possibility of infection due to manufacturing deficiencies*

**7.326** The Medicines Inspectorate found a number of deficiencies in buildings and facilities at the Edinburgh PFC on an inspection in 1981 and also deficiencies in manufacturing practices in a further inspection in 1988.<sup>598</sup> The 1981 Medicines Inspectorate report highlighted: (i) inadequate space in some production and storage areas; (ii) unsatisfactory processing conditions; (iii) poor surface finishes; (iv) unsatisfactory work flow patterns which could lead to product mix-up; and (v) unacceptable staff movements through production areas which could lead to contamination of components and products. The 1988 Medicines Inspectorate report highlighted: (i) staff structure; (ii) a need for review of documentation; (iii) a need to expedite the expansion of premises; and (iv) a need to remedy inadequacy of storage areas.

**7.327** Suspicion arose in the minds of some interested parties that the deficiencies identified in the 1981 report might have been connected to possible contamination of the SPPS used in Mr Tamburrini's case, or cast doubt on the identification of the materials used in his treatment. The specific question put by Messrs Thompsons, Solicitors, representing the patients, relatives and Haemophilia Society, was 'whether there is any potential link between the documented unsatisfactory state of affairs at Liberton in the 1980s and the possible infection of Mr Tamburrini with Hepatitis C as a result of the transfusion in September 1984'.<sup>599</sup> Professor van Aken was asked to consider these issues. He produced a supplementary report on them and gave oral evidence.<sup>600</sup>

**7.328** Professor van Aken set the scene.<sup>601</sup> The inspections were part of the ongoing process of implementing good manufacturing practices in a range of NHS premises where blood products for intravenous use were being manufactured at the beginning of the 1980s. That process took considerable time, especially in buildings and with facilities that

<sup>598</sup> Medicine Inspectorate 1981 Report [SNB.005.6826]; Medicine Inspectorate 1988 Report (draft only) [SNB.008.8791]

<sup>599</sup> Letter from Thompsons to Inquiry Solicitor dated 24 February 2011 [PEN.010.0386]

<sup>600</sup> Professor van Aken's supplementary report [PEN.011.0001]; Day 2, pages 56–57

<sup>601</sup> Ibid Day 2, pages 54–56

were constructed before the statement of manufacturing practice was written: it is easier to design facilities if one has a statement of manufacturing practice than it is to adapt something that already exists. He said that it was easily forgotten that, at that stage, 'the whole issue about safety and quality was different from now' and the introduction of good manufacturing practice was a major change, not just in the pharmaceutical industry but also in plasma fractionation. It required, on the one hand, that facilities were adapted and that equipment was changed and, on the other hand, that personnel were trained in a completely different way. A cultural as well as practical change had to happen. That could not be done overnight: time was required.<sup>602</sup> It is clear that the reports were part of an evolving scheme of regulatory oversight that involved the prescription of work required to upgrade facilities to meet new standards.

**7.329** Professor van Aken's initial view on the question posed by Messrs Thompsons was that, while he could not completely discount the proposition, he thought it highly unlikely that the noted problems with the PFC's production facilities had contributed to Mr Tamburrini's infection.<sup>603</sup> The evidence of Dr Cuthbertson was then disclosed to him,<sup>604</sup> which clarified the factual situation. The question posed had suggested to him that viral inactivation studies and manufacturing had not been carried out in separate environments (that is, in separate rooms) but they had, in fact, been separated: measures had been taken to reduce, minimise or completely avoid risk in this area.<sup>605</sup> The risk of mis-labelling and of mixing heated and unheated products had been considered. Dr Cuthbertson's statement gave him 'a good feeling that there is no question of mix-up between material which was pasteurised and material which was not pasteurised'.<sup>606</sup> The visual inspection step was common to all manufacturing facilities and the differences between pasteurised and non-pasteurised albumin products could be clearly seen.<sup>607</sup> He then referred to the possibility that batches could have been contaminated by the re-use of pH probes, especially if they had been used in 'virus-spiked' samples for experimental purposes. The process requirement of pasteurisation of already-sealed bottles excluded that, as did the fact that the Hepatitis C virus, which had not yet been isolated, could not have been in use at the PFC in 1983 in a way that might have contaminated probes.<sup>608</sup> He concluded that the potential link suggested in Messrs Thompson's question was 'impossible'.<sup>609</sup>

**7.330** He confirmed his views in answer to questions by Counsel representing the patients, relatives and the Haemophilia Society.<sup>610</sup> There is no basis for a view that a deficiency in plant or in the manufacturing processes at the PFC caused the issue of a product that may have caused Mr Tamburrini's infection.

**7.331** While in this context few scientific propositions can be expressed in terms of mathematical certainty, totally excluding alternative possibilities, it is, scientifically, most unlikely that the SPPS administered to Mr Tamburrini transmitted Hepatitis C. In conventional legal terms it was established, beyond reasonable doubt, that SPPS did not transmit Hepatitis C to Mr Tamburrini.

<sup>610</sup> Professor van Aken – Day 2, pages 65–67

### ***Possibility of infection in the course of surgery in 1998***

**7.332** The next possible candidate for transmission of infection that was explored was blood transfused on 14 December 1998 following Mr Tamburrini's surgery on 11 December 1998.<sup>611</sup> The mastectomy carried out was complicated by haemorrhage and he required evacuation of a haematoma and blood transfusion.<sup>612</sup> He was transfused with three units of packed red cells, one each from batches 707090QX, 611185X8 and 631627X1. A fourth unit from batch 707135Q3 was pierced and discarded unused.<sup>613</sup> He was discharged on 15 December.<sup>614</sup>

**7.333** Mr Tamburrini was diagnosed with cirrhosis in November 2001 and his liver failed to the extent that he required a transplant in October 2002, only some three years and ten months after the December 1998 operation. Dr Bathgate's view was that, in Mr Tamburrini's case, even four years was 'far too short' a period for liver failure as a result of his acquisition of Hepatitis C infection in 1998 to have developed.<sup>615</sup> Dr Mutimer's opinion was that the chances of acquiring Hepatitis C from a blood transfusion in 1998 were 'extremely low indeed' and he noted that, as mentioned in the GP's referral letter of 2 June 1998,<sup>616</sup> Mr Tamburrini already had abnormal liver function tests.<sup>617</sup> As referred to in paragraph 7.297, the gynaecomastia and other symptoms exhibited by Mr Tamburrini in 1998 were suggestive of existing liver disease.

**7.334** There were factors other than the issue of time that also tended to exclude the possibility of infection in 1998. Dr Myrtle Peterkin, clinical consultant to the West of Scotland Blood Transfusion Service, was contacted in September 2001 by Dr McLintock and agreed to follow up Mr Tamburrini's transfusion in 1998 as a possible source of his HCV infection. She investigated the sources of the blood components (packed red cells) transfused, and available to be transfused, to Mr Tamburrini in the course of the surgical procedures undertaken. She traced the process from the request for blood to cover the operation through to the record of transfusion. The respective donors' donating histories were traced and the history of the screening of those donations was reviewed.<sup>618</sup> Finally, the archived samples of the donations were repeat-tested with a PCR test for Hepatitis C.<sup>619</sup> Dr Peterkin reported on the outcome of her investigation in a letter of 17 October 2001 to Dr Isobel Walker.<sup>620</sup>

**7.335** In oral evidence, Dr Peterkin explained that this was a specific investigation. In ordinary course, the SNBTS did not trace or record the patients to whom blood and blood products were administered; rather, hospital blood banks recorded such use.<sup>621</sup> She was provided with details of the pack numbers derived from Mr Tamburrini's hospital record sheet and traced the records back from there. The records provided a complete audit trail from the transfusion of identified pack or batch numbers of individual units of red cells, prescribed and infused by named clinicians and countersigned by nursing staff, which were

<sup>621</sup> Day 2, page 3

correlated with records of the issue of the materials from the SNBTS.<sup>622</sup> From the records, the identities of the individual donors and the date of the donations were identified.<sup>623</sup> Dr Peterkin described what happened next with reference to one of the units:

It is important in cases like this that we don't just focus on the one donation; that is really critical. The index donation, which is why I highlighted it in bold, so that you can refer back to that – but as it were, to make assurance doubly sure that we are not missing any marker of infectivity, we look at the entire donating record. We actually retrieve archive samples from all the donations given and probe these donations as well for the specific markers that relate to the case in point.

So in this case we are talking about a possible Hepatitis C transmission and this is why we look at all those donations with specific references to the Hepatitis C virus, and ... all of the donations which were checked are Hepatitis C PCR negative, including the one that was given to the patient, and this donor had given two donations prior to November 1998, and so this is the full record of this donor that we have looked at.<sup>624</sup>

**7.336** The same procedure was carried out with each of the relevant units. The donations had been screened by anti-HCV screen when they were given. On this occasion the archived samples were also screened by HCV PCR test with negative results. Mr Tamburrini did not acquire Hepatitis C from red cells transfused at the time of surgery in December 1998.

### *Other possibilities*

**7.337** Excluding transfusion as a cause of infection does not exclude entirely the possibility of infection having been transmitted in hospital. Dr Mutimer commented:

We tend to forget that just being in hospital and having procedures done to us is associated with a risk of – transmission of infection, and that includes Hepatitis C infection. So although the blood products that he has been given are unlikely to be a cause of Hepatitis C transmission, you can never exclude the possibility that he came into contact with Hepatitis C infection during his medical care, not necessarily those inpatient admissions even; it could have been dental or medical treatment that he had at any time in his early life.<sup>625</sup>

**7.338** Dr Mutimer thought that Mr Tamburrini's teenage years might define a period of his life when he was more likely to have come into contact with Hepatitis C.<sup>626</sup> There are some issues relating to that estimate, given that it involved an assumption about experimentation with intravenous drug use, or association with others who used such drugs, for which there was no evidence. However, setting aside the speculation about drug use, Dr Mutimer's epidemiological data support the opinion that Mr Tamburrini may have been infected in his early teens. While that might indicate a period when transmission was more likely, it does not help identify the means of infection. The Inquiry heard no evidence concerning any other possible means of infection.

---

<sup>622</sup> GRI blood bank record [TAM.001.2463]; GRI IV Therapy prescription sheet [TAM.001.2918]; Day 2, pages 5–7

<sup>623</sup> Day 2, pages 7–9

<sup>624</sup> Ibid pages 9–10

<sup>625</sup> Day 1, page 114

<sup>626</sup> Ibid page 113

**7.339** The written closing submission submitted on behalf of patient interest core participants in relation to Mr Tamburrini's death states: 'In the circumstances the evidence that was heard by the Inquiry did not demonstrate even on the balance of probabilities how Mr Tamburrini came to be infected with Hepatitis C'.<sup>627</sup> That is an accurate statement.

**7.340** While the possibility of hospital-acquired transmission cannot be excluded absolutely, however, the evidence did establish, albeit to varying standards of probability, that none of the NHS procedures identified in Mr Tamburrini's case transmitted his Hepatitis C infection.

### **Possible date of infection with HCV**

**7.341** Having regard to the whole evidence covering this period, there is no room for doubt that Mr Tamburrini had well-developed Hepatitis C infection and cirrhosis by the end of 2001.<sup>628</sup>

**7.342** In a large statistical population of patients infected with Hepatitis C, the median time lapse between infection and cirrhosis of the liver in patients who do not have aggravating factors is about 30 years. At that stage half of infected patients will have developed cirrhosis and half will have less serious damage to the liver.<sup>629</sup> Men may progress more quickly than women. Consumption of alcohol will accelerate the progression to cirrhosis, as more fully discussed at paragraphs 7.345–7.346 below. In patients who acquired HCV infection under the age of 40, it is very rare for cirrhosis to be seen within 10 years of infection and it is uncommon to see it within 20 years of infection. Dr Mutimer's expertise in this area is extensive and his evidence is accepted as reliable. He had particular experience of patients requiring liver transplant procedures in Birmingham. He said:

[I]f I think of the patients that we transplant in Birmingham who have Hepatitis C, who look a little bit like Mr Tamburrini, then the majority of those will have been infected in their early adult years, late teens, early 20s. There will be a history of significant alcohol consumption, not necessarily alcoholism, and the average age at which they come to transplantation is approaching 55.<sup>630</sup>

**7.343** The extent to which Mr Tamburrini consumed alcohol was controversial and it is necessary to consider some of that evidence to ascertain whether it helps to determine at least an approximate period of time during which he was probably infected with Hepatitis C. In Mr Tamburrini's case, cirrhosis was diagnosed positively in November 2001.<sup>631</sup> He was approximately 44 years and seven months of age. At the date of his first liver transplant, in October 2002, he was 45 years of age, 10 years younger than the average age among Dr Mutimer's group of comparable patients infected in their teens or early twenties: Mr Tamburrini's Hepatitis C progressed to serious liver disease at a relatively early age. The duration of his underlying liver disease cannot be determined on the basis of these facts alone but they suggest a rapid progression of disease relative to the average.

**7.344** Progression to cirrhosis by the end of 2001, assuming a 30-year progression, would suggest a possible date of infection in about 1971, when Mr Tamburrini was about 14 years. Mr Tamburrini's teenage years appear to define the earlier end of the spectrum of

<sup>628</sup> Dr Mutimer's Report [PEN.010.0310] at 0311; Letter from the GRI to GP dated 13 December 2001 [TAM.001.2564]

<sup>629</sup> Dr Mutimer – Day 1, page 111

<sup>630</sup> Ibid page 112

<sup>631</sup> Letter from the GRI to GP dated 13 December 2001 [TAM.001.2564]

possibilities. The later end of the spectrum depends on whether alcohol was a contributory factor in the progression of his liver disease. If alcohol did accelerate the progression of the disease, he may have been infected in the later 1970s or early 1980s, in his early twenties, assuming a period of progression of 20–25 years, on the basis of the ranges provided by Dr Mutimer.

**7.345** The most complete scientific explanation of the role of alcohol in the progression of Hepatitis C was given by Professor Thomas. He said:

[I]t's now an accepted fact ... that alcohol increases the level of replication of Hepatitis C and, as a consequence, the liver damage that you see in someone who has Hepatitis C and is in addition taking significant amounts of alcohol, those two factors are synergistic; in other words, they cause more liver damage than the sum of the damage due to the alcohol and the Hepatitis C ... [B]efore we had ways of treating patients with Hepatitis C, one important thing to say was that you can slow down the progression of your Hepatitis C if you reduce your alcohol intake, and the ideal scenario would be that you would be abstinent from alcohol.<sup>632</sup>

**7.346** It was well understood by the later 1990s that significant alcohol consumption was associated with more rapid liver disease progression following Hepatitis C infection and with a higher likelihood of development of cirrhosis in those infected with Hepatitis C virus in young adulthood.<sup>633</sup> That alcohol might have, not merely an additive, but a synergistic effect on the progression of Hepatitis C virus infection was suggested around 2004–05 as a result of studies of factors that altered understanding of the effectiveness of replication of the virus.<sup>634</sup> 'Significant' was not quantified in this context. The official guidance set out in the Scottish Intercollegiate Guidelines Network (SIGN) publication 'Management of hepatitis C – A national clinical guideline' published in 2006 and repeated in the updated version published in 2013, is that: 'Even moderate amounts of alcohol (within government recommended guidelines) have been associated with increased liver fibrosis compared to those who abstain'.<sup>635</sup>

**7.347** The issue for the purposes of this discussion is whether Mr Tamburrini's consumption of alcohol assists in determining the period within which he acquired Hepatitis C infection. Detailed analysis of his medical records showed a pattern of persistent alcohol use over a period. The earliest reference to 'alcohol consumption in excess' dates from 1995.<sup>636</sup> From then until March 2002 there are about 10 instances of reports that expressly, or by reasonable implication, indicate that statements were made by Mr Tamburrini that he had been consuming significant quantities of alcohol.

**7.348** Dr McLintock's letter of 8 August 2001 (referred to above in paragraph 3.300), following examination at the GRI Haematology Clinic, narrated that Mr Tamburrini had reported his alcohol consumption as at least 20 units of alcohol per week and

<sup>636</sup> Summary of GP Records 1968–2004 [TAM.001.1459] at 1460

frequently more, normally of beer and red wine.<sup>637</sup> Dr McIntock reviewed Mr Tamburrini on 5 September 2001. On this occasion he reported mild success in cutting down his alcohol intake.<sup>638</sup> When seen at the Gastroenterology Clinic in November 2001, following Dr McIntock's reference, Mr Tamburrini is recorded as reporting a five-year history of drinking approximately 80 units of alcohol per week, which he claimed to have cut down by that date.<sup>639</sup> He was thought 'clearly' to have decompensated chronic liver disease from a combination of alcohol and Hepatitis C.<sup>640</sup>

**7.349** On 17 December 2001, Mr Tamburrini was seen at the GRI Liver Clinic by Dr Stanley. He was said to have been keeping fairly well and to have reduced alcohol consumption to a glass of wine every week or two.<sup>641</sup>

**7.350** In January and February 2002, Mr Tamburrini attended the GRI Gastroenterology Unit for tests and was referred to the Liver Transplant Unit (LTU) at the RIE for assessment for transplantation.<sup>642</sup> He reported that he had been off alcohol for three months.<sup>643</sup> After attendance at the LTU on 25 February 2002, the discharge report dated 5 March sent to Mr Tamburrini's GP and copied to Dr Stanley commented on a number of matters including the consumption of alcohol.<sup>644</sup>

**7.351** The letter of 5 March 2002 provided a careful and detailed professional review of Mr Tamburrini's history to the end of February 2002. It indicated that his period of abstinence was shorter than reported at the end of 2001 and followed a long period of sustained drinking: 100 units a week of wine and beer over the previous eight years. He had managed to remain abstinent for about six weeks in November and December 2001 but had relapsed at Christmas time and at that stage he was drinking five to six units per week.<sup>645</sup> On his referral from Liaison Psychiatry, at the RIE, to Psychiatry at Parkhead Hospital, Glasgow it was noted that, on review of the GRI notes, Mr Tamburrini had been told to abstain from alcohol on at least two occasions. He was asked by the transplant team to abstain completely.<sup>646</sup>

**7.352** At that time, Mr Tamburrini was referred to the Community Alcohol Service of Greater Glasgow Primary Care NHS Trust where he was seen by a Community Psychiatric Charge Nurse, Audrey Ewing (later Audrey Russell, after her marriage). There, he gave an account of seven years of heavy drinking which had escalated to 50–100 units of alcohol per week over five days when he had worked in the public house trade. Before that he drank very little. He said that, when very young, he had experimented with drugs, later identified as amphetamines and cannabis.<sup>647</sup> He did not keep follow-up appointments at the Community Alcohol Service, cancelling many.<sup>648</sup> By August, however, he had completed all relapse-prevention sessions and his support from the Service was terminated.<sup>649</sup>

**7.353** While the reports show wide variation in the volume of alcohol reportedly consumed, the overall picture presented was of significant and sustained consumption. As reported by Dr Seonaid McCallum of the Department of Psychological Medicine, at the RIE, to Dr Jauhar, Consultant Psychiatrist, at the Parkhead Hospital, on 6 March 2002, psychiatric examination disclosed that:

Initially Mr Tamburrini denied that he had an alcohol problem but during ... interview he admitted that indeed, although he had managed to stop drinking, sustained abstinence was a problem for him. He also had limited insight into the effect excess alcohol can have in conjunction with hepatitis C and was unaware that it can cause accelerated liver failure. I felt that at the end of the interview he was beginning to show some motivation and insight into his alcohol problem. He did not give a history of alcohol dependency, rather his problem was one of harmful alcohol use.<sup>650</sup>

**7.354** As reported by Dr McCallum, Mr Tamburrini had given a history of drinking 50–100 units of alcohol per week. He had achieved a six-week period of abstinence before Christmas which he had been unable to maintain. Dr Mutimer considered that psychiatric assessment as perhaps the most expert undertaken during Mr Tamburrini's psychological assessment for liver transplantation.<sup>651</sup> His evidence is accepted. It is to be noted that Dr McCallum's view was that Mr Tamburrini's problem was of harmful alcohol use, particularly in the context of his HCV infection, of which he was unaware until 2001. It is nowhere suggested that he was 'an alcoholic' or otherwise dependent on alcohol.

**7.355** Dr Mutimer said of Mr Tamburrini:

In my opinion, both hepatitis C virus infection and alcohol caused cirrhosis and subsequent hepatic decompensation. It is not possible to determine the relative contributions of hepatitis virus infection and alcohol to his liver damage. The duration of his hepatitis C infection is unknown. It is possible that he was infected with hepatitis C at a young age ....It is also possible that he was infected at a much later date .... At times in his life, his alcohol intake was excessive and certainly sufficient to cause liver damage. His reported (or at least documented) alcohol consumption varies quite significantly. Perhaps the most expert assessment would have been undertaken during his psychological assessment for liver transplantation. That assessment stated that he consumed 50 to 100 units of alcohol per week for eight years.<sup>652</sup>

He underwent liver biopsy in August 2002. The liver biopsy showed that he had a micronodular cirrhosis and that the changes were consistent with chronic hepatitis virus infection. At that time, there were no particular signs of alcoholic liver damage. This observation is not surprising and does not exclude alcohol as a significant cause of his liver damage. It seems likely that he was abstinent from alcohol during all of 2002 and that his alcohol consumption during the last quarter of 2001 was not excessive. I believe that the histological changes associated with alcoholic liver damage could have resolved during his

---

<sup>650</sup> Dr McCallum's letter [TAM.001.0905]

<sup>651</sup> Dr Mutimer's report [PEN.010.0310] at 0313

<sup>652</sup> The psychological assessment carried out by Dr McCallum [TAM.001.0905] refers to 50–100 units per week and to 'drinking to excess over the last 5 years'. The reference to drinking 100 units a week over eight years is in the letter from Dr MacGilchrist's registrar dated 5 March 2002 [TAM.001.2524]. Dr Mutimer has conflated the two sources.

period of abstinence. Indeed the hepatologists in Edinburgh would have been encouraged by the histological appearances which would have reassured them that there was no significant recent alcohol intake. In summary, I believe that hepatitis C and alcohol contributed to his liver disease.<sup>653</sup>

**7.356** Dr Bathgate and Dr Mutimer both commented on consumption of alcohol as a possible factor which might have contributed to Mr Tamburrini's underlying liver disease. Dr Bathgate described experience in south east Scotland which indicated that alcohol was the major co-factor seen in cases such as Mr Tamburrini's.<sup>654</sup> Dr Mutimer was more positive: Mr Tamburrini's underlying liver disease was secondary to HCV infection and alcohol. He was, however, unable to determine their relative contributions.<sup>655</sup>

**7.357** The reports of alcohol consumption were not challenged as inaccurate records of what Mr Tamburrini told medical staff. It was submitted that the basis on which the amounts were 'estimated' was not known but the written records indicate that they reflect what Mr Tamburrini told the physicians and other relevant health care professionals, including Nurse Audrey Ewing. The reports were clearly not believed by the family's wider circle, however. Mrs Tamburrini and friends of the family submitted affidavits in which they stated variously that Mr Tamburrini did not drink heavily.<sup>656</sup> Mrs Tamburrini has stated that in the late 1980s her husband did not drink during the week, except perhaps for celebrations, and did not drink excessively. When he began working in licensed premises, he would have a couple of beers with his friends but they did not have money to drink heavily. She did not recall any increase in his drinking when he began bar work. They had both abstained in 1996 for a period. She comments that the family are incredulous that it should be recorded in the medical records that he drank 50–100 units of alcohol a week.<sup>657</sup> Mr Charlie Cunningham never saw Mr Tamburrini drink to excess. He would have a couple of drinks in a night club. He did not recall any escalation in his drinking when he started working in the bar.<sup>658</sup> Mr Stephen Clocherty said that, at the fruit market, because of the early start, Mr Tamburrini would not have been able to stay out late drinking. He did not see any change when Mr Tamburrini went to work in the bar. He thought that it was 'pure nonsense' to say that he drank 50–100 units of alcohol a week.<sup>659</sup> Mr Fisher, the owner of the establishment where Mr Tamburrini worked, said that no one drank at work. During the week they would have a bottle of beer while tidying up. At weekends they would sometimes have two or three drinks before going home. He remembered Mr Tamburrini being advised to stop drinking before his first transplant. He never saw him drink anywhere near 50–100 units of alcohol a week.<sup>660</sup>

**7.358** There are three significant problems with this evidence. In the first place, some of it does not relate to the period over which Mr Tamburrini is likely to have been developing liver disease. Mrs Tamburrini met her husband in 1987.<sup>661</sup> Mr Fisher knew him as brother-in-law of Mrs Tamburrini and speaks of no earlier acquaintanceship.<sup>662</sup> Mr Cunningham and Mr Clocherty knew Mr Tamburrini from school and from work but speak of very

<sup>661</sup> Statement of Mrs Jean Tamburrini [PEN.001.0309]

<sup>662</sup> Affidavit of Bernard Fisher [PEN.018.1559]

general impressions only. Secondly, in the nature of things, the witnesses could never give more than impressions from observation of Mr Tamburrini's drinking when they were present. Thirdly, standing the records, the evidence contradicts what Mr Tamburrini himself told medical staff. Balancing these statements against contemporaneous records of Mr Tamburrini's own statements, the witnesses' affidavits cannot be accepted as reliable evidence of Mr Tamburrini's consumption of alcohol over the period when he was developing significant liver disease, which probably began long before 1987.

**7.359** Further, the evidence is misdirected so far as the issues before this Inquiry are concerned. It has not been suggested that Mr Tamburrini was generally adversely affected by alcohol, or drank to excess in any conventional sense that implies drunkenness. As noted above, Dr McCallum's view was that Mr Tamburrini's problem was of harmful alcohol use, particularly in the context of his Hepatitis C virus infection. In the progression of HCV-related liver disease, even moderate alcohol consumption may play a part in accelerating damage. On his own reports there were clearly long periods when Mr Tamburrini drank alcohol regularly.<sup>663</sup> He frequently reported consumption, inconsistently as to amount, at periods when his developing symptoms could have been related, in whole or in part, to his alcohol habit. The conditions reported in Mr Tamburrini's medical records and described above frequently have plausible associations with alcohol.

**7.360** It is not possible to quantify precisely the effect of alcohol in the progression of Mr Tamburrini's liver disease. However, accurate estimates of quantity are unnecessary in light of the expert evidence led. On the evidence of the medical records, there was a pattern of alcohol consumption over a period of years that was highly likely to have accelerated the progression of liver disease due to his infection with Hepatitis C. It made it more likely that he would become one of the minority of those infected at a young age (under 30 years) who develop cirrhosis sooner rather than later.

**7.361** Given a relatively short period of progression from infection to cirrhosis, the history narrated above nevertheless indicates that alcohol was a contributory factor. That was the view of the medical witnesses, which is accepted.

**7.362** As set out in paragraphs 7.299–7.300 above, Mr Tamburrini's abnormal blood parameters found in 2001 were thought by his clinicians at the time to be indicative of liver disease. Dr McLintock thought that their most likely cause was liver disease probably caused by alcohol. Mr Tamburrini had reported his consumption to her as 20 units per week.<sup>664</sup> Dr Mutimer commented that, in Mr Tamburrini's case, the gynaecomastia reported earlier in 1998 would be consistent with alcoholic liver damage, with HCV infection, and also with damage due to both alcohol and HCV infection. His MCV recorded at that time was in keeping with alcohol excess.<sup>665</sup> Some medications used to treat patients with advanced liver disease can also cause gynaecomastia but there is no record of Mr Tamburrini taking such medications at the time.<sup>666</sup> The medical evidence was consistent: by the end of 2001 there was established liver disease, consistent with the consumption of alcohol and Hepatitis C.

**7.363** In January 1999, when suffering from acute pancreatitis, Mr Tamburrini was advised to abstain from alcohol. Choledocholithiasis (the presence of stones in the bile

<sup>666</sup> Dr Mutimer – Day 1, pages 94–95

duct) and excess alcohol consumption are both important causes of acute pancreatitis. Either might have precipitated the episode of pancreatitis he had at this time.<sup>667</sup> From the contemporaneous medical records, his pancreatitis was clearly thought to be related to some extent to his drinking, although it was formally recorded that it might have been due to preceding viral infection.

**7.364** As discussed at paragraph 7.355, it is accepted that Mr Tamburrini was abstinent from alcohol from late 2001 until his death in November 2004. Alcohol did not contribute to the failure of either the first or second liver transplant grafts received by Mr Tamburrini or cause, or contribute to the cause of, his death. It is accepted that the cause of death was unrelated to alcohol consumption. The progression of his liver disease following transplantation was independent of those factors.

**7.365** In summary, consumption of alcohol was a contributory factor in the progression of Mr Tamburrini's liver disease to cirrhosis at a relatively young age.

### Later progression of disease

**7.366** On 12 November 2001, an abdominal ultrasound scan was carried out at the GRI liver clinic.<sup>668</sup> There were changes consistent with liver cirrhosis and it was decided to proceed to Magnetic Resonance Imaging (MRI) scan.<sup>669</sup> The MRI scan on 20 November 2001 showed underlying cirrhotic change in the liver, with liver cirrhosis, especially in the right lobe. There was no underlying focal mass and no evidence of hepatoma (liver cancer)<sup>670</sup> and there was no overt portal hypertension (high blood pressure around the liver).<sup>671</sup> However, albumin levels indicated advanced liver impairment and raised alphafetoprotein (AFP) levels suggested the possibility of hepatoma despite the negative scans.<sup>672</sup> Dr Stanley reported to Mr Tamburrini's GP on 13 December that there were a few spider naevi (visible red lines on the skin indicative of cirrhosis of the liver) on examination but no definite ascites (fluid in the abdomen, a marker of liver function).<sup>673</sup>

**7.367** On 28 November 2001, Mr Tamburrini was reviewed at the GRI Haematology Clinic by Dr Maclean. It was noted that significant macrocytosis (abnormally large red blood cells indicative of anaemia) persisted.<sup>674</sup> On 17 December, he was seen at the Liver Clinic by Dr Stanley. He was said to have been keeping fairly well. Rising AFP levels were still of concern and thought to indicate the need for a liver biopsy.<sup>675</sup> On 8 January 2002, Dr Stanley noted an AFP level of 366 and thought the rising pattern suggested hepatoma.<sup>676</sup> Dr Mutimer explained that the magnitude of the AFP level was informative. If it was in the thousands, that almost always meant that there was liver cancer. When it was in the hundreds, as it was in Mr Tamburrini's case, then it could simply be associated with an inflamed liver rather than with cancer but tests would be performed to exclude the possibility of liver cancer.<sup>677</sup> Investigations proceeded on 7 February 2002. A contrast enhanced three phase scan and an ultrasound scan confirmed underlying liver cirrhosis but there was no

<sup>674</sup> Letter from the GRI to GP dated 20 December 2001 [TAM.001.2563]

<sup>675</sup> Letter from the GRI to GP dated 15 January 2002 [TAM.001.2562]

<sup>676</sup> Letter from the GRI to GP dated 25 January 2002 [TAM.001.2561]

<sup>677</sup> Day 1, page 106

underlying hepatic mass. Gastro-oesophageal varices and varices along the lesser curve of the stomach were identified. The impression was of underlying liver cirrhosis, with overt portal hypertension (pressure within the portal vein from the liver is increased and may lead to bleeding) but no hepatoma.<sup>678</sup> Dr Stanley wrote to Mr Tamburrini's GP on 15 February with these results.<sup>679</sup>

**7.368** On 14 February 2002, Dr Stanley referred Mr Tamburrini to Dr Simpson, consultant hepatologist at the RIE LTU for assessment.<sup>680</sup> At that time, there remained some concern that Mr Tamburrini had developed primary liver cancer.<sup>681</sup> Dr Stanley was concerned about a rising level of AFP in his blood test, an indication of possible hepatocellular cancer. That was a legitimate concern at the time but events were to show that Mr Tamburrini did not have hepatocellular cancer. Dr Stanley reported that two ultrasound scans, an MRI scan and a contrast CT scan<sup>682</sup> had been carried out which disclosed liver cirrhosis, varices, and stones in the gall bladder but no splenomegaly (enlargement of the spleen). No scan had shown evidence of underlying hepatocellular cancer but ascites and poor synthetic liver function were noted.<sup>683</sup>

**7.369** Mr Tamburrini was admitted to the RIE LTU on 25 February 2002.<sup>684</sup> Dr MacGilchrist's registrar reported to Mr Tamburrini's GP, copied to Dr Stanley, following discharge on 2 March 2002. The discharge letter, dated 5 March, commented on past medical history, as understood at the time, clinical findings, test results and consumption of alcohol.<sup>685</sup> Comprehensive tests were carried out. Mr Tamburrini was cytomegalovirus (CMV) and Hepatitis C positive.<sup>686</sup> Dr Bathgate thought that the results showed moderate impairment of liver function at this stage.<sup>687</sup> Cirrhosis was confirmed during the assessment for liver transplant. Because Mr Tamburrini reported that he was still drinking alcohol he was thought not to be a suitable candidate for transplant: prior to becoming eligible for listing for liver transplant, a period of abstinence (usually six months) is required. In the meantime, other tests were carried out to follow up the risk of hepatoma.<sup>688</sup> It seems clear that Mr Tamburrini remained abstinent from alcohol from this time, as instructed.

**7.370** He was reviewed at the RIE LTU on 4 April 2002.<sup>689</sup> His AFP level had fallen. A CT scan using Lipiodol, a contrast medium, was carried out shortly before his clinic appointment and the results were 'against him having hepatocellular carcinoma'.<sup>690</sup> A triple-phase CT scan carried out on 21 June did not indicate any focal abnormality of his liver.<sup>691</sup> He was to be reviewed in six weeks.<sup>692</sup> Mrs Tamburrini recollected that monthly reviews were arranged.<sup>693</sup> In July, his AFP had risen again and Dr Stanley asked the LTU to ensure early reassessment.<sup>694</sup>

<sup>692</sup> Ibid [TAM.001.0881] at 0883

<sup>693</sup> Witness Statement of Mrs Jean Tamburrini [PEN.001.0309] at 0312

<sup>694</sup> Letter from the GRI to the RIE LTU dated 3 July 2002 [TAM.001.2533]

**7.371** He was seen at the LTU on 4 July 2002. His AFP level was seriously raised, as were other levels. The recent CT scan results were thought to indicate that the AFP level indicated ongoing Hepatitis C activity rather than the presence of a tumour. Further review in two months was arranged.<sup>695</sup> Dr Bathgate thought that the AFP level noted on 4 July was quite concerning.<sup>696</sup>

**7.372** Mr Tamburrini was re-admitted to the LTU on 13 August 2002 for formal liver transplant assessment. After extensive review, including liver biopsy, Dr MacGilchrist's registrar reported at length to Mr Tamburrini's GP. There was cirrhosis with mild ongoing inflammation thought to be due to Hepatitis C. He was CMV and HCV positive. The conclusion at that stage was that there was increasing active viral replication but no indications of hepatocellular carcinoma and transplantation was to be delayed as long as possible in view of the fact that he was asymptomatic of liver disease.<sup>697</sup>

### *The decision to proceed with a liver transplant*

**7.373** Mr Tamburrini next attended the LTU on 10 October 2002. By this stage, Dr Simpson noted that he was becoming more symptomatic. He was increasingly tired and having to sleep during the day. He was not sleeping at night. He was getting night cramps. The reversal of his sleep pattern was an indication of early encephalopathy (brain dysfunction).<sup>698</sup> His weight was increasing and he felt swelling in his ankles and abdomen. His AFP level had fallen further. Following examination it was decided to admit him on 17 October and list him for liver transplantation.<sup>699</sup>

**7.374** He was admitted on 17 October but found to be very unwell. Mrs Tamburrini explained that her husband's health had started to deteriorate rapidly by this point.<sup>700</sup> He had become confused and jaundiced. He complained of fever and abdominal pain over three days. On examination he was septic and had evidence of spontaneous bacterial peritonitis. He was treated intensively. At this stage, Mr Tamburrini signed a contract of alcohol abstinence and was officially put on the transplant waiting list and allowed home on 25 October.<sup>701</sup>

**7.375** However, on that day a suitable donor liver was found and he was re-admitted. He had a liver transplant on 26 October 2002. He required intensive care and treatment after the operation. There were complications of bacterial peritonitis and renal impairment (which resolved without the need for dialysis). He progressed to a good recovery and was allowed home on 15 November 2002.<sup>702</sup> No hepatocellular cancer was found in the explanted liver.<sup>703</sup>

### *Post-transplant observation*

**7.376** On 19 November 2002, Mr Tamburrini attended a planned post-operation review at the LTU. He complained of abdominal pain. Clinically, he appeared unwell and in obvious pain and was admitted for investigation.<sup>704</sup> There was free fluid within the abdomen.

<sup>702</sup> Ibid [TAM.001.0874]

<sup>703</sup> Ibid [TAM.001.0874]

<sup>704</sup> Letter from the RIE LTU to GP dated 13 December 2002 [TAM.001.0872]

After extensive tests, it was found by ERCP procedure (endoscopic examination)<sup>705</sup> that there was a leak from his bile duct at the anastomosis, the biliary connection with the implanted liver. The ERCP was complicated by pancreatitis but the stricture was dilated and a stent was inserted to try to stop the leak. It was anticipated that he would require to be re-admitted for assessment of the need for further surgery of the anastomosis.<sup>706</sup> He was discharged home on 13 December. Dr Mutimer thought that inflammation from the recurrence of Hepatitis C and poor drainage via the bile duct as a result of the stricture were both relevant to subsequent damage of the implanted liver.<sup>707</sup>

**7.377** Mr Tamburrini attended Dr MacGilchrist's clinic on 17 December 2002. A report was sent to his GP.<sup>708</sup> On discharge, Mr Tamburrini remained generally well, with no abdominal pain and reduced drainage of fluid. The prospect of further surgery to renew the connection was kept open. He was reviewed on 14 January 2003 and an ultrasound examination showed a normal liver with no evidence of collection around his biliary tree.<sup>709</sup> He reported at a clinic appointment on 28 January feeling well and said that he was thinking of going back to work.<sup>710</sup>

**7.378** Mrs Tamburrini reported that, after discharge, her husband lost the previous excess fluid and recovered his normal condition. He received medication to prevent rejection of the implanted liver.<sup>711</sup>

**7.379** After a clinic visit on 27 February, Mr Tamburrini was admitted to the LTU for further examination on 10 March 2003. Tests confirmed that there was no obvious debris or stones. There was a suggestion of focal hepatic artery stenosis (narrowing), possibly at the anastomosis, with very turbulent flow. An ERCP procedure was carried out on 11 March. Ultrasound examination and ERCP showed that the bile duct was dilated above an anastomotic stricture. This required placement of a new endoscopic stent. Mr Tamburrini's bilirubin level fell slowly, which suggested that the endoscopic stent was providing biliary drainage.<sup>712</sup> Treatment of his possible hepatic artery stenosis was deferred.<sup>713</sup>

**7.380** Mr Tamburrini was reviewed in April and June 2003. It was decided to continue monitoring his condition.<sup>714</sup> On 24 July 2003, he was reviewed at the LTU when he reported feeling much better. At that stage, it was thought that his biliary stent should be removed in September.<sup>715</sup> It was arranged that he would be admitted for his annual biopsy following a holiday in October.<sup>716</sup> Mrs Tamburrini reported that, on 27 August 2003, at a family event, he was bloated and jaundiced.<sup>717</sup> The ERCP was repeated in September 2003. This showed that the anastomotic stricture persisted. The stent which had been placed six months earlier was not visible. In September it was decided that no further intervention should take place.<sup>718</sup>

<sup>716</sup> Ibid [TAM.001.0832]

<sup>717</sup> Witness Statement [PEN.001.0309] at 0313

<sup>718</sup> Letter from the RIE LTU to GP dated 11 September 2003 [TAM.001.0830]

**7.381** The couple went on holiday but Mr Tamburrini's sleeping pattern was disturbed and he again became jaundiced. His ankles and abdomen were swollen.<sup>719</sup> He was seen at the LTU on 6 November 2003. His symptoms of 'obstructive' jaundice were noted. Further tests were arranged with specific reference to the state of his hepatic artery.<sup>720</sup>

**7.382** Additional investigations were performed at about that time. These were highly technical. There were differing opinions about what was shown and in particular whether there was restriction of blood flow. The appearance of the biliary tree was similar to that shown on previous ERCP scans. There was a new finding of multiple upper abdominal fluid collections of uncertain nature. Liver biopsy showed established cirrhosis with evidence of recurrent and active Hepatitis C infection. It was decided to repeat ERCP and stenting across the anastomotic stricture. Antiviral treatment was also considered.<sup>721</sup> It was noted at that stage that his Hepatitis C was Genotype 1.<sup>722</sup> Dr Bathgate explained that Genotypes 1, 2 and 3 are commonly found in Scotland. Antiviral therapy for Genotype 1 usually requires 12 months with a success rate of less than 50%, whereas treatment for Genotypes 2 and 3 requires six months with an 80% success rate. Treatment is less effective in individuals with cirrhosis and after liver transplant.<sup>723</sup> Mr Tamburrini's prospects were relatively poor.

**7.383** On 4 December 2003, Mr Tamburrini was seen by Dr Bathgate and treatment of his Hepatitis C was discussed.<sup>724</sup> Poor liver function persisted. Dr Bathgate thought that Mr Tamburrini was unlikely to tolerate any treatment in his then existing state.<sup>725</sup> Options would be discussed in January. Dr Bathgate thought that treatment of the Hepatitis C would have to have been 'fairly aggressive', given his history.<sup>726</sup> In January 2004, his condition deteriorated seriously and he was confused, disorientated and jaundiced.<sup>727</sup> He was admitted on 13 January to the RIE. Again tests showed evidence of cirrhosis likely to be secondary to Hepatitis C. Hepatitis C had returned and he needed a second transplant.<sup>728</sup>

### **Second liver transplant**

**7.384** A donor liver became available on 4 February and he had a second liver transplant operation.<sup>729</sup> The surgeon found a dilated and thickened donor bile duct. There was also portal vein thrombosis. Dr Mutimer considered that the appearance of the donor bile duct suggested that biliary complications (in addition to the recurrent Hepatitis C infection) had probably contributed to the development of cirrhosis and graft failure.<sup>730</sup> He expanded on his views in oral evidence. He thought that, during the first year post-transplant, the team were clearly having problems with the bile duct. It was his impression that they thought they had largely resolved that problem but that the finding of the dilated, thickened bile duct at the time of re-transplantation suggested that perhaps that was a problem which had not, in fact, been completely resolved.<sup>731</sup>

---

<sup>719</sup> Witness statement of Mrs Tamburrini [PEN.001.0309] at 0313

<sup>720</sup> Letter from the RIE LTU to GP dated 13 November 2003 [TAM.001.0824] at 0825: the problem so noted was not restricted to obstruction. It indicated that the liver was working very badly and could properly have been described as 'cholestatic'.

<sup>721</sup> Letter from the RIE LTU to GP dated 8 December 2003 [TAM.001.0814] at 0815

<sup>722</sup> Specifically Genotype 1A. But the distinction between 1A and 1B is not relevant for present purposes. See Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.14 for discussion of HCV genotypes.

<sup>730</sup> Dr Mutimer's report [PEN.010.0310] at 0312

<sup>731</sup> Day 1, pages 108–109

**7.385** Mr Tamburrini developed post-operative biliary peritonitis secondary to a leaking enterostomy. Further treatment and surgery was required. He made an eventual recovery from that admission<sup>732</sup> and was discharged on 28 February, with a recall date in March to consider antiviral treatment for Hepatitis C.<sup>733</sup> Mr Tamburrini was examined on 16 March 2004 and it was found that his liver function tests had deteriorated.<sup>734</sup> The clinicians were concerned that he was susceptible to aggressive Hepatitis C recurrence.<sup>735</sup> He was to be reviewed by Dr Bathgate, with in-patient ultrasound and liver biopsy examinations.<sup>736</sup> Thereafter, antiviral therapy with a combination of Interferon and Ribavirin was commenced during in-patient care between 23 and 29 March and he had a further liver biopsy. A report was sent to his GP: he was to return for review on 8 April. At this stage, Mr Tamburrini was seen by the specialist Hepatitis C nurse and told what to expect from the treatment.<sup>737</sup>

**7.386** Mr Tamburrini continued to attend hospital. On 22 April 2004, he was reported to be tired, lacking in energy and looking unwell although he did not complain of being depressed. In contrast, Mrs Tamburrini had noted that he was grumpy at this time.<sup>738</sup> Mr Tamburrini showed considerable fortitude throughout this period. The antiviral treatment caused diarrhoea. Balancing treatment against his tolerance was necessary.<sup>739</sup> His HCV level was measured on a number of occasions during antiviral therapy. Despite the therapy, his HCV level remained extremely high and there was no obvious improvement from the therapy.<sup>740</sup>

### *A grave prognosis*

**7.387** Mr Tamburrini was an in-patient at the RIE from 1 to 15 June 2004. Among the tests carried out, liver biopsy showed fibrosing cholestatic hepatitis (an aggressive type of Hepatitis C generally seen in patients who are immunosuppressed)<sup>741</sup> caused by recurrent Hepatitis C.<sup>742</sup> The prognosis was very grave and there were few options for treatment.<sup>743</sup> Antiviral therapy was increased and other elements of his therapy were re-balanced. He required the additional use of erythropoietin and other haematologic growth factors.<sup>744</sup> He was reviewed again, on 15 July and 6 September.<sup>745</sup> On 14 September liver ultrasound had been unable to detect flow in the portal vein. There was a cystic collection in the left lobe of the liver as well as splenomegaly and moderate ascites. A further liver biopsy was carried out. His treatment now involved the optimum dose of pegylated Interferon and Ribavirin, which he managed to tolerate well, but he required blood transfusions every two to three weeks to counter side-effects of the Ribavirin treatment.<sup>746</sup>

**7.388** Despite treatment, his condition deteriorated. On 7 October 2004, he was again admitted to the RIE. He was suffering from severe lethargy and fatigue, weight loss and significant depression. He had a fever and was treated with antibiotics. He developed increasing hepatic decompensation, with increasing ascites and episodes of recurrent encephalopathy. He required paracentesis, the drawing off of fluid. A third transplant could not be considered. The antiviral treatment was stopped. His care regime was changed from aggressive therapy to palliative care after discussion with Mrs Tamburrini. He died on 17 November 2004.<sup>747</sup>

### **Mr Tamburrini's treatment and management**

**7.389** Asked to comment on whether Mr Tamburrini's treatment and management were appropriate Dr Mutimer said in his report:

[Mr Tamburrini] clearly had significant liver damage prior to the diagnosis of Hepatitis C virus infection in October 2001. His medical attendants assumed that the abnormal liver function tests were due to the consumption of alcohol. The hospital admission with possible pancreatitis was also in favour of an alcoholic aetiology for the abnormal liver function tests. In general, alcohol-induced pancreatitis is only seen in patients with quite high levels of alcohol consumption. I cannot determine from the medical files if attempts were made to engage the patient with services that might modify his alcohol consumption. That would have been appropriate. Eventually, he developed overt liver failure. It was appropriate that he was screened for viral hepatitis. That confirmed hepatitis C infection. His subsequent management seemed entirely appropriate. He was advised to abstain from alcohol and largely achieved that. He underwent appropriate psychological assessment. He was placed on the liver transplant waiting list and underwent liver transplantation. All of that seemed quite appropriate. He had significant complications after transplantation. Those complications principally involved damage to the bile duct. This is a recognised complication after liver transplantation and attempts to investigate and manage the biliary problems seem entirely appropriate. It is possible, however, that inadequate drainage of the bile duct contributed to liver damage and the development of cirrhosis. It was quite reasonable to attribute the rapid development of cirrhosis (in the transplanted liver) to the hepatitis C infection. Certainly it would have made a significant contribution. It is recognized that re-transplantation for aggressive Hepatitis C infection can be associated with aggressive recurrence in the second transplanted liver. Therefore, it was quite reasonable and appropriate to plan for early antiviral therapy after re-transplantation. It was appropriate that antiviral therapy was deferred pending resolution of the early post-operative complications. Indeed, antiviral therapy was commenced six weeks after re-transplantation at a time when liver graft function was good and biopsy confirmed that little damage had been experienced.<sup>748</sup>

**7.390** In Dr Mutimer's opinion, antiviral therapy appeared to have been fully clinically justified: the physicians were concerned that aggressive Hepatitis C recurrence would lead to early graft damage and graft failure. The use of erythropoietin and growth factors

---

<sup>747</sup> Letter from the RIE LTU to GP dated 22 November 2004 [TAM.001.0740]; Dr Bathgate – Day 1, pages 70–72

<sup>748</sup> Dr Mutimer's Report [PEN.010.0310] at 0314

enabled the continued administration of antiviral therapy despite suppression of the bone marrow. Suppression of the bone marrow including the leucocytes may have contributed to infection. As the patient died, there was a complicated picture of marrow suppression, possible infection and serious liver damage. Dr Mutimer stressed that, while the drugs administered were 'very toxic', in his opinion there was nothing wrong in the decision to administer the drugs or in the way they were administered, under the circumstances.<sup>749</sup>

**7.391** Dr Mutimer concluded his assessment of the appropriateness of Mr Tamburrini's treatment and management:

Despite antiviral therapy, it appears that there was very aggressive hepatitis C recurrence with development of significant liver damage by June 2004. Under that circumstance, it was quite reasonable to persist with antiviral therapy. Unfortunately, antiviral therapy can have quite significant haematologic side effects. The patient would have been susceptible to infection. Susceptibility to infection would have been a consequence of liver dysfunction and bone marrow suppression. In summary, I believe that this man's treatment and management were appropriate.<sup>750</sup>

**7.392** That assessment of the position is accepted.

### Cause of death

**7.393** The cause of death as given in the death certificate was liver transplant graft failure and recurrent Hepatitis C.<sup>751</sup> Dr Bathgate agreed with the causes given.<sup>752</sup> In his opinion, the transplant graft failure was caused by Mr Tamburrini's Hepatitis C infection. Severity was a function of several factors, including the concentration of the virus and the age at which the patient's own liver had deteriorated. The younger a person was when infected, the worse the likely outcome following liver transplantation. It was likely that Mr Tamburrini was in that category. In Dr Bathgate's view, Mr Tamburrini was at 'the worst end of the spectrum' of Hepatitis C infection.<sup>753</sup>

**7.394** Dr Mutimer thought that the final cause of death was difficult to ascertain but that contributing factors were aggressive Hepatitis C recurrence and antiviral therapy. Available antiviral treatment was a challenge when given to patients who were as sick as Mr Tamburrini and who were receiving so many other medications. It was recognised that the toxicity of antiviral treatment was much greater in that setting than in giving the drugs to the average non-transplant patient with Hepatitis C. He thought that Mr Tamburrini did have significant side-effects from the antiviral drugs. Dr Mutimer used these drugs in treating his own post-transplant patients and they suffered many of the same problems. In his view, Mr Tamburrini died as a consequence of HCV infection and the antiviral therapy that was required in his case. Dr Mutimer's evidence that antiviral therapy, though appropriate, was a contributory factor to mortality is accepted.<sup>754</sup>

## Conclusions

**7.395** Factors contributing to the death of Mr Tamburrini were:

- (i) A clinically severe form of Hepatitis C.
- (ii) Acceleration of cirrhosis after the first transplant associated with problems at the site of the biliary anastomosis which probably led to hepatic artery impairment, local leak of bile and infection, and the portal vein thrombosis found at the operation for his second liver transplant.
- (iii) Profuse HCV replication after the second transplant probably associated with further biliary and vascular problems, which led to accelerating cirrhosis and fibrosing cholestatic hepatitis.
- (iv) Liver transplant graft failure.
- (v) The antiviral treatment given to prevent damage to the second graft.

**7.396** Infection with Hepatitis C:

- (vi) On the evidence available, with the exception of the possibility of hospital acquired infection, it was established to varying standards of probability that the known NHS procedures in Mr Tamburrini's case did not transmit Hepatitis C infection:
  - a. On a balance of probabilities, having regard to the whole evidence available, Mr Tamburrini was not transfused at the time of his appendicectomy operation in 1968.
  - b. It was proved beyond reasonable doubt that SPPS did not transmit Hepatitis C to Mr Tamburrini in 1984.
  - c. It was established beyond reasonable doubt that Mr Tamburrini did not acquire Hepatitis C from red cells transfused at the time of surgery in December 1998.
- (vii) No connection was demonstrated between any deficiency in plant or process at the PFC and the infection of Mr Tamburrini with Hepatitis C.
- (viii) On epidemiological grounds, it is likely that Mr Tamburrini acquired HCV infection in his late teens or early 20s.
- (ix) The cause of that infection is unknown.

**7.397** Progression of disease:

- (x) Mr Tamburrini had probably developed advanced liver disease by July 1998.
- (xi) His gynaecomastia was likely to have been a symptom of that disease.
- (xii) Consumption of alcohol was a contributory factor in the progression of Mr Tamburrini's liver disease to cirrhosis, and the need for the first transplant in October 2002.

**7.398** Mr Tamburrini's management as a patient:

- (xiii) Mr Tamburrini's care and management as a patient were appropriate.

**7.399** Alcohol as a cause of death:

- (xiv) Consumption of alcohol did not contribute to the failure of either the first or second liver transplant grafts received by Mr Tamburrini, or cause, or contribute to the cause of, his death. It is accepted that the cause of death was unrelated to alcohol consumption.

## CHAPTER 8

### KNOWLEDGE OF HIV/AIDS NOW

#### Introduction

**8.1** As in the case of the Hepatitis C virus (HCV), discussed in Chapter 13, *Knowledge of Viral Hepatitis Now*, an understanding of the current knowledge of HIV infection and the progression to AIDS is necessary for a proper appreciation of the accounts provided by patients and their relatives of experiences of HIV infection, narrated in Chapter 5. The forms of drug therapy associated with the treatment of HIV infection, with particular reference to the side-effects of treatment, are also discussed.

**8.2** This chapter provides an account of what is known now, in 2014, about HIV infection and the AIDS complex of diseases, in particular in relation to the two affected groups identified in Chapter 2, *Patients at Risk*: bleeding disorder patients receiving therapy and patients infected by blood transfusion in the course of medical or surgical procedures.

**8.3** Unlike HCV infection, the AIDS epidemic, so far as it affected those groups, struck NHS patients over a relatively short period of time and the response of scientists and clinicians alike was rapid and concentrated. This chapter is correspondingly short.

#### HIV and AIDS: an overview

##### *Cellular immunodeficiency*

**8.4** The Acquired Immune Deficiency Syndrome (AIDS) was first reported in July 1981 as a new acquired cellular immunodeficiency, exclusively in homosexual men.<sup>1</sup> At that time, it was already known that disorders or disturbances of the immune system might arise from a variety of causes. Primary immune deficiency, with which the patient was born, or which developed without a known external cause, was an area of established clinical expertise in one or two centres in the UK.<sup>2</sup> Secondary immune deficiency was known to arise from certain drugs, cancers or viral infections. Cytomegalovirus and Hepatitis B virus (HBV) infection were both examples of viral infections already known to influence the immune system and, initially, there was speculation that one or the other of these, or possibly a new, more virulent strain of one or other of them, might be the causative agent of AIDS as many of the individuals affected were positive on testing for both of these viruses.<sup>3</sup> It was also suggested that recreational drugs used by the male homosexual population might be the cause, with amyl nitrate briefly proposed as a candidate.<sup>4</sup>

**8.5** In the course of 1982 a syndrome very similar to that reported in homosexual men was identified, again in the USA, first in intravenous drug users (IVDUs) and then in a few individuals with haemophilia. It was therefore suggested that blood-borne transmission was a possibility.<sup>5</sup>

<sup>5</sup> Professor Lever's Report [PEN.015.0517] at 0520

**8.6** While other views have persisted and still persist, there is now a very strong general consensus that AIDS is a condition caused by a blood-borne virus, the Human Immunodeficiency Virus (HIV). Developments towards that consensus are discussed in Chapter 11, *HIV/AIDS Aetiology*. For present purposes, it is sufficient to note some key events and the short period of time over which they developed.

**8.7** The AIDS virus was first isolated in 1983 by researchers in France from a patient with enlarged lymph glands and was called 'lymphadenopathy-associated virus' (LAV).<sup>6</sup> It was not, however, generally accepted that this virus was the cause of AIDS until researchers in the USA reported, in 1984, on the isolation of what proved to be the same virus from a number of patients with AIDS.<sup>7</sup> The first US isolates were named 'Human T-cell Lymphotropic Virus Type III' (HTLV-III) because of an assumed association with two other viruses, previously identified by the same research group, that specifically attacked T lymphocytes – immunologically active white blood cells.<sup>8</sup> In 1986 the virus was renamed Human Immunodeficiency Virus (HIV) by the International Committee on Taxonomy of Viruses.<sup>9</sup> It is now widely agreed that HIV-1 is the principal agent of transmission of AIDS. In this discussion, where it is necessary to distinguish the disease from other immune deficiency conditions, the term HIV/AIDS will be used.

**8.8** HIV/AIDS emerged as the most serious issue for people with haemophilia and for those involved in treating them, or preparing products for their use, in the period 1981–85. By 1985, the virus, HIV, had been identified and steps could be taken to prevent its transmission by blood and blood products. Tragically, many patients were already infected and deaths from AIDS mounted among haemophilia patients during the late 1980s and beyond. From 1981–89, while non-A, non-B Hepatitis/Hepatitis C remained a problem both in relation to blood products and transfusion of whole blood and blood components, HIV/AIDS dominated the medical, scientific and political scene.

### *AIDS: the progressive deterioration of the body's immune system*

**8.9** AIDS is a condition which arises from the progressive deterioration of the body's immune system, leaving the patient prone to opportunistic infections and malignant diseases. The clinical manifestations of infection (the 'AIDS complex' of diseases) are very variable and widespread throughout the body but all ultimately stem from an impaired immune response. This can be the immune response to infections or a failure of the body's 'immune surveillance' of possible cancer cells. Since HIV can establish itself inside the body's lymphocytes for a period of time without damaging or destroying the lymphocytes, an individual can be 'HIV-positive', and infectious to others, while having no overt illness for a period of months or years.

**8.10** Many of the infections associated with HIV/AIDS are either rare or more severe than in patients who do not have HIV infection or AIDS. For example, tuberculosis bacilli (TB) probably appear randomly in the environment and many people may be exposed to

<sup>6</sup> Barré-Sinoussi et al, 'Isolation of a T-lymphotropic Retrovirus from a Patient at Risk of Acquired Immune Deficiency Syndrome (AIDS)', *Science*, 1983; 220:868–871 [LIT.001.0058]

<sup>7</sup> Gallo et al, 'Frequent Detection and Isolation of Cytopathic Retroviruses (HTLV-III) from Patients with AIDS and at Risk for AIDS', *Science*, 1984; 224:500–503 [LIT.001.3769]

<sup>8</sup> They were the third type of virus found by researchers that specifically attacked the T cells of humans, hence the designation HTLV-III.

<sup>9</sup> The Varmus Committee was convened by Dr Harold Varmus, Chair of the Retrovirus Study Group within the Vertebrate Virus Sub-committee of the International Committee on Taxonomy of Viruses. See: <http://socialarchive.iath.virginia.edu/xtf/view?docId=varmus-harold-cr.xml>. There are, in fact, known to be at least two main types of HIV viruses. HIV-1 is responsible for the worldwide pandemic of AIDS while HIV-2 is mainly confined to West Africa. (See Chapter 11 *AIDS Aetiology*, paragraph 11.10 for further brief discussion of HIV-1 and HIV-2).

them in small quantities from time to time. Normally, the immune system can deal with these few TB organisms and exposure does not lead to the development of tuberculosis, whether or not the individual has been vaccinated against the disease. In HIV patients, by contrast, exposure may lead to tuberculosis more readily and in a relatively severe form. The same situation arises with many other unusual pathogens, as well as various, usually extremely rare, forms of cancer – for example the vascular cancer Kaposi's sarcoma. As noted in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.118, it is also now known that, in individuals co-infected with HIV and HCV, the development of severe chronic liver disease from HCV occurs more frequently and more rapidly than if the patient is infected with HCV alone.

**8.11** Initially, diseases of the AIDS complex proved to be rapidly fatal in many cases once overt disease was diagnosed. There was fear of a pandemic and, in response, a huge investment in research into the condition and means of identifying infection and providing treatment.

### **Biology of HIV**

**8.12** HIV/AIDS plays a central role in this Report and some understanding of the biology of HIV is important in providing an insight into the clinical and epidemiological manifestations of the disease, which form one of the core themes of the Report. An account of the biology of HIV, much of it drawn from the written and oral evidence of Professor Andrew Lever, Professor of Infectious Diseases at Addenbrooke's Hospital, Cambridge, is therefore given here.

**8.13** In some viruses, genetic material has a DNA form: Hepatitis B is an example. DNA is a very stable molecule. It is easy to replicate very accurately. HIV is a ribonucleic acid (RNA) virus. RNA is a much less stable molecule than DNA. RNA viruses mutate (change their genetic information) much more readily.

**8.14** The processes by which viruses generally use the protein-synthesising machinery of a living cell to replicate (make new copies of themselves) are described in the context of HCV infection in Chapter 13, *Knowledge of Viral Hepatitis Now*.<sup>10</sup> Like other viruses, HIV can replicate only if it can attach to a cell and thereafter enter it. In order to do this the virus requires that the surface of the cell provides a suitable receptor to which the virus particle can 'dock'.

**8.15** Some individuals cannot be infected with HIV because they are effectively protected by a mutation of their lymphocyte cells which prevents HIV particles from docking. Other individuals are infected but appear to be able to maintain a normal immune response which suppresses the virus for many years. In each group variant genetic patterns may result in disease progress being inhibited.<sup>11</sup>

**8.16** Apart from such exceptional cases, the process typically begins when an HIV particle attaches itself to the surface of a cell bearing the immune recognition complex CD4 on its surface, and specifically the protein CCR5. This can be one of the protective cells in the blood that ingests infectious agents, known as macrophages, or it can be a particular type of lymphocyte, the T-helper lymphocyte, a type of white blood cell that plays a crucial role

---

<sup>10</sup> Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraphs 13.22–13.23

<sup>11</sup> Professor Lever – Day 26, pages 20–21

in maintaining the function of the human immune system. After attaching to the cell, the virus converts its RNA into DNA by the use of an enzyme called reverse transcriptase. The viral DNA is transported to the cell's nucleus, where it is spliced into the human DNA.

### *The reproductive process*

**8.17** Once integrated into a cell, the virus may begin replicating immediately or may lie dormant within the infected cell for months, or even years. Cells do not malfunction on incorporation of the viral DNA: the viral DNA is very small, comprising about 10,000 individual nucleotides (the building blocks of DNA), a tiny number compared to the 30 million or so nucleotides that make up human DNA. Additionally, it almost always inserts in places which do not disrupt the normal functioning of the cellular DNA.<sup>12</sup> When the cell which the virus has entered becomes activated, it treats the HIV genes within it in much the same way as its own (human) genes. The virus DNA within the cell contains the data from which information is transcribed into RNA. When the RNA produced is trafficked out of the nucleus into the cytoplasm of the cell (the gel within the cell membrane) it carries a code which instructs internal cell sub-structures to assemble the amino acids required to produce the viral proteins of HIV. Where the transcription process is effective, the protein is a new RNA copy of the HIV virus.

**8.18** The result is that new HIV viral particles are formed and released, thereby starting the replication process all over again. HIV can replicate rapidly, with several billion new viruses made every day in a person infected with HIV. However, HIV is a very imperfect virus in terms of effective replication: it has a notoriously high 'particle to infectivity ratio'. Of the total number of virus particles to which an individual is exposed, only a very small minority are actually functional, capable of transmitting infection, and are harmful. An individual exposed to a million virus particles might only be exposed to 10 which could do any harm.<sup>13</sup>

**8.19** During replication HIV mutates and evolves. Reverse transcriptase often makes random mistakes in the transcription process from RNA to DNA. As a result, new types or strains of HIV (with slightly different DNA) develop in a person infected with the virus. Because of changes in the DNA the proteins of the virus will be different, making it harder for the individual's already compromised immune system to 'recognise' or to respond to and deal with the virus. By the time the immune system has developed antibodies to one strain, mutation has resulted in new strains, increasing the risk that the virus will evade the immune defences. On the other hand, many of the mutations that occur are lethal for the virus because they interfere with some important protein that the virus needs for survival.

**8.20** A further factor affecting the variability of HIV is that it can undergo a process of 'recombination'. Each virus particle carries two copies of its genes. During replication, the virus can take pieces from either copy to make up the final product. If a cell is infected with two different viruses, then sometimes the virus picks pieces from a copy of each. Then, when the recombination occurs, the resulting virus is a mixture of the genetic sequence of the two apparent viruses it came from and this also makes the virus extremely variable. This process probably has a more important impact on variability than the fact that the enzyme, reverse transcriptase, makes mistakes.<sup>14</sup>

---

<sup>12</sup> Ibid pages 12–13

<sup>13</sup> Ibid pages 62–65

<sup>14</sup> Ibid page 64

**8.21** In a person infected with HIV, the virus destroys billions of CD4 T-helper lymphocyte cells every day, eventually overwhelming the immune system's capacity to regenerate or fight infection.

**8.22** Professor Lever commented:

HIV has proven to be so far impossible to develop a vaccine against because it is hugely variable. Every time it replicates it mutates at least once and probably five or ten times.

Without being too technical, the virus ... is made up of RNA and there are about 10,000 individual nucleotides making up the RNA of the virus. We know that the enzyme that copies it makes a mistake about once every 10,000 bases, so it makes a mistake every time it replicates. Within an infected individual, even when they are well, they are producing around 10 to the 11th, which is 100 billion viruses every day, and they are mutating at the rate I mentioned, which means that in one infected person, every single one of the 10,000 nucleotides is being mutated at least once every day. So the variability of that virus is enormous.

....

This means that if you are infected once with HIV, you have a family of viruses which develop from that infection and certainly by sexual transmission, you probably only get infected by a small number, a handful of viruses. But you get a family that derive from that handful and rapidly become very large. If you are repeatedly exposed, you are going to be exposed to different variants, and because those variants can recombine, then the resulting diversity of viruses that you can get is going to be even larger.

So multiple exposures is a bad thing for increasing the diversity of the virus that your immune system has to encounter, and again this would be something which would not have been obviously predictable from other infections that we knew about [at the time of discovery of HIV].<sup>15</sup>

**8.23** At the start of the AIDS epidemic, it was known that in the case of some chronic infections, such as Hepatitis B, while some people were relatively poor at clearing the virus and a proportion of these became chronic carriers, the majority of healthy individuals did appear to be able to clear it and develop immunity from re-infection. This experience informed the common notion at the time that exposure to infectious agents usually gave a level of protection against further infection by the same virus. A perception had arisen that, having been exposed to a virus, it was not going to harm the individual to be exposed to the same virus again because either the immune system would have developed sufficient immunity to protect the individual completely or because it would help to suppress the second exposure. However, almost without precedent at the time, it was to emerge that, in the case of HIV, prior exposure to the virus gave no protection against infection on further exposure.<sup>16</sup> As noted in Chapter 13, *Knowledge of Viral Hepatitis Now*, a similar discovery was later to emerge in the case of HCV.<sup>17</sup> Immunity from further infection does

<sup>15</sup> Ibid pages 63–65

<sup>16</sup> Ibid pages 60–61

<sup>17</sup> Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.38

not follow from clearance of infection with the virus. The more exposures there are, the more likely it is that the individual will be exposed to one which infects them successfully.

### **Transmission**

**8.24** HIV is found in the blood, semen and rectal and vaginal fluid of those infected with the virus. It cannot survive for very long outside the body. The main modes of transmission are: sexual intercourse; intravenous drug use (through the use of shared, contaminated needles); receiving a transfusion of infected blood or blood products; and perinatally (ie from infected mothers to their children at or around the time of birth, from infected maternal blood or through breast feeding). The route of infection affects the range of AIDS-related diseases to which the individual is exposed. Patients treated with blood products and others infected with HIV by blood-borne routes rarely presented with Kaposi's sarcoma, in contrast to gay men for whom this was an early and ongoing feature of AIDS.<sup>18</sup>

### **Testing**

**8.25** When an individual becomes infected with HIV, antibodies to the virus are produced but, unlike the case in most other infections, these antibodies have little or no ability to neutralise the virus. The antibodies are, however, used in laboratory tests as a marker for the presence of HIV. Tests which detect antibodies to HIV include enzyme-linked immunosorbent assay (ELISA) and Western blot tests. Detectable antibodies are usually produced within two to six weeks of infection, at which point a patient has 'seroconverted', although sometimes the period may be up to three months. Accordingly, the ELISA and Western blot laboratory tests may not detect infection in an individual who has been infected very recently with HIV (ie up to three months after infection, often referred to as the 'window period' between infection and seroconversion).

**8.26** A different type of test, polymerase chain reaction (PCR) tests, detect the presence of HIV itself, through detection of its genetic material, rather than the presence of antibodies to the virus. PCR testing may be undertaken to detect the presence of the virus before as well as after seroconversion and therefore may be used in the 'window' between the time the individual acquires HIV infection, and becomes infectious to others, and seroconversion. PCR tests are more time-consuming and expensive than ELISA and Western blot tests for antibodies, however, and are therefore unsuitable for use in screening large numbers of blood samples.

### **Symptoms and pathology**

**8.27** In the first few weeks after infection with HIV, most people experience few, if any, symptoms. A month or two after infection, individuals may experience a flu-like illness, including fever, headache, tiredness and enlarged lymph nodes in the neck and groin area. The symptoms usually disappear within a week to a month after their onset and are often mistaken for another viral infection such as glandular fever or influenza (flu). During this period, people are highly infectious. There then follows a period during which the body's immune system fights the virus and the disease remains clinically inapparent (clinically latent).

---

<sup>18</sup> Professor Lever – Day 26, pages 75–76. See Chapter 11, *AIDS Aetiology*, paragraph 11.43 for a possible explanation for the discrepancy between homosexual men and others with AIDS in relation to presenting with Kaposi's sarcoma.

**8.28** Over time, however, the immune system deteriorates to the point at which it is unable to fight off other infections. The rate of progression to symptomatic diseases associated with AIDS varies greatly from person to person and may take many years. Hence, when the disease was first reported, it was initially estimated that only a minority of patients infected with HIV would go on to develop AIDS.<sup>19</sup> It is now known, however, that, if untreated, the vast majority of patients who contract HIV are likely to go on to develop secondary 'opportunistic' infections or tumours (diseases of the 'AIDS complex') which, in the absence of treatment, are likely eventually to result in death.

### *Symptomatic disease*

**8.29** Understanding of the association between HIV infection and the symptomatic diseases identified in patients with AIDS has changed over time.<sup>20</sup> When HIV was recognised as causing AIDS, it was initially perceived that the effect was limited to the immune system and would therefore predispose the individual to infections and, as it turned out, infection-related cancers. Professor Lever explained the gradual progression of understanding from this point:

[A] number of additional medical conditions became apparent in patients with HIV infection, such as degeneration of the kidney, and HIV-associated brain disease, and it was realised that, by mechanisms which weren't always completely obvious, HIV was affecting other systems directly, and that when treatment for HIV came along and the virus load was successfully suppressed, these conditions would reverse.

That was a phase in which everything was potentially put down as attributable to HIV infection. More recently, I think, there is a more balanced feeling that a lot of what goes wrong in someone who is HIV-infected is HIV-related but that HIV-infected people get diabetes and get other conditions, so there is, I think, a more ready acceptance, particularly in the fact that the HIV population is now becoming an ageing population, that the diseases which affect ageing populations without HIV are affecting people with HIV.<sup>21</sup>

**8.30** Many cancers fall into that category. Professor Lever explained:

There is a general background increase in the incidence of almost all malignancies in patients with HIV because your immune system not only fights infections but has a role in eliminating malignant cells. So that if you have an advanced immunodeficiency and you lack the sort of lymphocytes which can recognise that a cell has become cancerous, then that cell has a greater chance of developing into a full-blown malignant tumour.<sup>22</sup>

**8.31** The 'age-related' risk in a long-term infected individual described by Professor Lever is still less than the risk of more directly virus-induced cancers, such as Kaposi's sarcoma or non-Hodgkins lymphoma, of which an increasing range has been identified.

<sup>19</sup> In 1986, for example, a UK Government advisory body stated that only 1 in 10 people with HIV were likely to go on to develop AIDS: DHSS Advisory Committee on Dangerous Pathogens, 'Revised guidelines on LAV/HTLV III – the causative agents of AIDS and related conditions' [DHF.002.1456] at 1463

<sup>20</sup> Professor Lever – Day 26, page 7

<sup>21</sup> Ibid pages 7–8

<sup>22</sup> Ibid page 146

**8.32** Within the group of infections that are HIV-related, the secondary infections that may develop include a variety of fungal, viral and bacterial infections of the mucous membranes and skin. However, a type of pneumonia caused by a fungal infection called *Pneumocystis jirovecii* (previously known as *Pneumocystis carinii* pneumonia and often still abbreviated to PCP) remains the most common life-threatening secondary infection in patients who progress from chronic HIV infection to AIDS.<sup>23</sup>

**8.33** AIDS may also affect the nervous system, not only with the development of secondary infections such as cerebral toxoplasmosis (leading to the formation of abscesses in the brain) but also directly as in progressive multi-focal leucoencephalopathy (progressive damage or inflammation of the white matter of the brain) and peripheral neuropathy (damage to the nerves of the peripheral nervous system). Patients may also suffer psychiatric disorders including depression.

**8.34** Without treatment, patients eventually develop end-stage disease, both secondary to having little immunity and from direct viral effect such as in progressive multi-focal leucoencephalopathy, and death becomes inevitable from one or more of the above or related conditions.

## Treatment

### *Drug therapy for HIV/AIDS*

**8.35** Throughout the 1980s, when the HIV/AIDS epidemic began, after the initial relatively asymptomatic period lasting for a variable number of years, people infected with the virus were unlikely to live longer than two or three more years from the time of the development of one or more of the AIDS-defining illnesses. Until 1986 there was no specific treatment for HIV. Patients were treated with the appropriate therapy for any HIV-related condition they presented with, such as PCP, thrush or a viral infection.<sup>24</sup> In general, without treatment, 50% of patients with AIDS survived one year but only 20% survived three years from the identification of an AIDS-defining illness.<sup>25</sup> Today, the prognosis for most of those infected with HIV is much better as a result of the availability of effective antiretroviral medication. There are six main groups of antiretroviral drugs presently available to treat the disease, each of which attacks the virus in different ways. The classes are: nucleoside reverse transcriptase inhibitors (NRTI); non-nucleoside reverse transcriptase inhibitors (NNRTI); protease inhibitors; fusion inhibitors; entry inhibitors and integrase inhibitors.<sup>26</sup> The development of drug therapy was initially slow but then accelerated, as indicated below.

**8.36** Zidovudine (also known as AZT), an NRTI drug, became available for patients on a named patient basis<sup>27</sup> from late 1986 and was licensed for use in 1987.<sup>28</sup> A study in 1986 suggested that patients with HIV had a longer rate of survival when prescribed Zidovudine and also that the rate of opportunistic infections was reduced.<sup>29</sup> Despite early

<sup>26</sup> Ibid [PEN.012.1044] at 1055

<sup>27</sup> ‘Named patient basis’ meant that, if a clinician considered that a patient would benefit from a medication prior to it being licensed, the clinician could request access to the medication for this patient from the manufacturers. Professor Leen, Day 33, pages 20–21

<sup>28</sup> Professor Leen – Day 33, page 20. Zidovudine became available for the treatment of AIDS in Scotland on 1 April 1987: SHHD letter to General Managers [SNB.004.8395].

<sup>29</sup> Professor Leen – Day 33, page 20; Professor Leen’s Report [PEN.012.1044] at 1049. Though not specifically identified by Professor Leen, it is likely that the study was: Fischl et al ‘The efficacy of azidothymidine (AZT) in the treatment of patients with AIDS and AIDS-related complex. A double-blind, placebo-controlled trial’ *New England Journal of Medicine* 1987; 317(4):185–91

indications that it did inhibit the virus, clinical trials of the drug showed that it did not improve the long-term outlook for patients.<sup>30</sup> Between 1987 and 1993, two additional HIV drugs, Didanosine (DDI) and Zalcitabine (DDC) were undergoing clinical trials. These drugs were the same type of drug as Zidovudine (NRTIs). DDI and DDC were introduced in 1991 and 1992 respectively and clinicians started prescribing them to patients with HIV, again on a named patient basis. These, like AZT, tended to be used as single agent therapy (monotherapy).

**8.37** As stated above, HIV replicates very rapidly. As a result of this, Zidovudine (like the other NRTIs) on its own was not strong enough to completely prevent replication of the HIV virus and the treatment led to only a short-lived improvement in the patient's clinical condition.<sup>31</sup> For patients with late-stage AIDS, Zidovudine was associated with an improved prognosis of no more than two years.<sup>32</sup> In the event, monotherapy against the virus with any of these early drugs proved to be of little use. HIV quickly becomes resistant to a single drug and the drug stops being effective.<sup>33</sup> The early use of Zidovudine and disappointment at its lack of real efficacy is reflected in the accounts of patients and their families in Chapter 5.

**8.38** The practice of using drugs singly reflected the history of drug therapy in other diseases. There was a tendency to use each new drug one at a time; partly because they became available in that way, and partly because of a lack of perception at that time of the fact that some infectious agents can mutate to get around therapeutic agents. It has now become more generally accepted that more than one drug, working by more than one antiviral mechanism, should be used to provide additional hurdles for some viruses or other pathogens to overcome.<sup>34</sup> In the treatment of HIV infection, two or more antiretroviral drugs came to be prescribed at the same time, thereby reducing the rate at which resistance developed and making treatment more effective in the long term.<sup>35</sup> However, the view of Professor Clifford Leen<sup>36</sup> of these drugs was that, at the early stage of development of drug therapy, their effectiveness was '[p]retty poor actually. It was still a death sentence .... Even using two drugs ... still did not hold the virus at bay.'<sup>37</sup> As noted below at paragraph 8.43, from 1998 a combination of three different drugs came to be prescribed with the result of a great improvement in outcomes.

**8.39** Persistence with drug therapy is essential to its success. It is likely that 90–95% of prescribed treatment needs to be taken for the best chance of treatment to work.<sup>38</sup> Failing to adhere to this level of treatment results in the even more rapid emergence of drug resistance and the subsequent failure of HIV treatment and immunological deterioration.<sup>39</sup> When Zidovudine was first prescribed in 1987 it was recommended that the doses be taken every four hours. This meant that patients had to wake themselves up during the night to take a dose. This then had a knock-on effect on a patient's tiredness and must have

<sup>37</sup> Professor Leen – Day 33, page 39

<sup>38</sup> Studies have shown that 90% to 95% of protease inhibitor therapy doses must be taken for optimal viral suppression. Professor Leen – Day 33, pages 53–54; Professor Leen's Report [PEN.012.1044] at 1049; Paterson et al, 'Adherence to protease inhibitor therapy and outcomes in patients with HIV infection' *Annals of Internal Medicine*. 2000; 133:21–30 [LIT.001.5525]

<sup>39</sup> Professor Leen's Report [PEN.012.1044] at 1063; Professor Leen – Day 33, pages 52–53

caused some anxiety about remembering to take the tablets on time.<sup>40</sup> The importance of full adherence to antiviral medication is now understood and patients receive adherence support from a number of professionals including clinical nurse specialists, dieticians, their doctor and sometimes a counsellor. In 2001, the British HIV Association issued guidelines about the adherence support a patient should receive. In contrast, those patients treated in the 1980s and early 1990s received very little support in adhering to their medication. There was, and is, difficulty in persuading children and teenagers in particular to take such medication.<sup>41</sup> Difficulties in keeping to quite complex treatment regimes for drugs are reflected in the evidence and statements of patients and relatives described in Chapter 5.

**8.40** These early treatments were also associated with many side-effects, affecting many organs, which added to patients' difficulties in adhering to therapy as well as having direct impact. These side-effects included headache, nausea, vomiting, diarrhoea, flatulence, skin rashes, liver inflammation, kidney stones, dysphoria (disquiet or restlessness), weird and sometimes frightening dreams, depressive symptoms, tiredness, poor sleep and body shape changes.<sup>42</sup> Didanosine can cause pancreatitis which can be debilitating. People with this condition have to fast and, if a patient is thin anyway from AIDS, they will become thinner due to this condition. Didanosine can also cause peripheral neuropathy (inflammation of the nerves) which can cause painful feet and hands.<sup>43</sup> Body shape changes are particularly distressing for patients. There are two different types of body shape changes that are seen. One change is fat loss, usually around the face and on the arms and legs. Patients' veins become prominent as a result of the fat loss in the arms, legs and buttocks. The facial fat loss is the most distressing as the patient appears to have lost weight and looks like an unwell AIDS patient with late-stage HIV disease. The other body shape change is fat accumulation around the belly and back of the neck. This can co-exist with the fat loss and the combination makes the patient's appearance quite abnormal.<sup>44</sup> Body shape changes can be stigmatising and distressing, often resulting in low self-esteem, isolation and depression, as reflected in the account of his illness described by the patient given the pseudonym 'Mark'.<sup>45</sup> These side-effects led many patients to stop their HIV medication.

### *Development in drug therapy from the early 1990s*

**8.41** Against this background, there was a clear incentive for research and the development of drug therapy and there was rapid development from the early 1990s.<sup>46</sup> Some of the principal developments are indicated in Table 8.1 below. Approval for use in the UK generally followed within a few months of approval by the Food and Drug Administration (FDA) in the USA.<sup>47</sup> The use of these drugs will be illustrated in Chapter 5, in the narrative of the experiences of individual patients.

**Table 8.1: Development of Antiretroviral Drugs**

Year approved by US FDA	Name	Type
1987	Zidovudine	NRTI
1991	Didanosine	NRTI
1992	Zalcitabine	NRTI
1994	Stravudine	NRTI
1995	Saquinavir	Protease Inhibitor
	Lamivudine	NRTI
1996	Ritonavir	Protease Inhibitor
	Indinavir	Protease Inhibitor
	Nevirapine	NNRTI
1997	Delavirdine	NNRTI
	Nelfinavir	Protease Inhibitor
1998	Efavirenz	NNRTI
	Abacavir	NRTI
1999	Amprenavir	Protease Inhibitor
2000	Lopinavir + Ritonavir	Protease Inhibitor
2001	Tenofovir	NRTI
2003	Atazanavir	Protease Inhibitor
	Fosamprenavir	Protease Inhibitor
	Entricitabine	NRTI
	Enfuvirtide (T-20)	Fusion Inhibitor
2005	Tipranavir	Protease Inhibitor
2006	Darunavir	Protease Inhibitor
2007	Maraviroc	Entry Inhibitor
	Raltegravir	Integrase Inhibitor
2008	Etravirine	NNRTI

**8.42** The arrival of protease inhibitors from 1995–96 heralded a dramatic improvement in the treatment of HIV. The early drugs in the protease inhibitor class were associated with a tendency towards increased bleeding times, however, so that haemophilia patients often needed more clotting replacement therapy at the same time as their HIV treatment.

**8.43** The first British consensus statement on the treatment of HIV was published in *The Lancet* in April 1997 and revised in 1998. British guidance has been frequently updated since then.<sup>48</sup> In 1998 the British HIV treatment guidelines recommended the use of triple therapy in patients with HIV. This was the start of the Highly Active Anti-Retroviral

<sup>48</sup> Professor Leen's Report [PEN.012.1044] at 1045

Treatment (HAART) era.<sup>49</sup> Clinicians could now put together a 'cocktail' of three drugs to administer at the same time, severely restraining the ability of the virus to develop resistance.<sup>50</sup>

**8.44** Since then, further drugs have been developed, as noted in the table above. The wide range allows for additional flexibility in the selection of components of the dual and triple therapy prescribed. In addition, the way in which these newer drugs are formulated has allowed much simpler and better tolerated dosing regimes. The use of triple HIV combination therapy led to sustained suppression of HIV replication. This then allowed the immune system to reconstitute and, as a consequence, marked and sustained clinical improvement was expected. When full suppression of HIV replication is achieved, HIV drug resistance does not emerge.<sup>51</sup>

### *Treatment regimes and side-effects of therapy*

**8.45** For young people (and most of the haemophilia patients infected were boys), the treatment regimes could prove to be difficult. Apart from side-effects, the medication could be difficult to take and the routine was sometimes resisted. Some teenagers found the tablets difficult to swallow and found the taste unpleasant. They also had real problems in adhering to the regime and some stopped taking their medication regularly. Some tablets had to be taken with food but some patients could not manage to eat regularly. Patients were routinely advised that they should not discontinue drug therapy since, if they did, HIV symptoms would come back with a vengeance. In some cases, however, late teenaged boys stopped taking their medication. Some may have got to a point where they just decided to let nature take its course. Specific examples are described in Chapter 5. For immediate purposes, it is sufficient to note that these accounts give substance to the general observations of clinicians and others that adherence to drug therapy was, and remains, demanding.

**8.46** For many patients, young and not so young, side-effects of antiretroviral treatment were serious. Some patients developed thrombocytopenia (a reduction in the number of red blood cells) and treatment had to be suspended for a period. Examples are set out in Chapter 5.

**8.47** Since treatment regimes were demanding and side-effects could be debilitating, it became important for clinicians to know whether to persist with a particular course of treatment. In 1997, British HIV Association Guidelines for antiretroviral treatment of HIV patients recommended that 'viral load measurement' should be made widely available to physicians. Viral load is a test that measures the amount of HIV virus in the bloodstream. Originally available only in research laboratories, it first became generally available in clinics in August 1996.<sup>52</sup> Clinicians learned that if a patient's viral load was detectable while on the treatment, HIV drug resistance was likely to emerge. This test also allowed clinicians to explore responses to HIV drugs. They learned that if the patient was taking his/her medication appropriately and the HIV viral load was undetectable then, over time, their immune system would recover. Furthermore, if their viral load was undetectable, they were at much lower risk of developing new opportunistic infections.<sup>53</sup>

<sup>52</sup> Professor Leen's Report [PEN.012.1044] at 1052

<sup>53</sup> Ibid [PEN.012.1044] at 1052; Professor Leen – Day 33, pages 47–48

**8.48** An 'HIV resistance test' started to become available from 2000 onwards. This test allows clinicians to predict which HIV drugs are likely to be most effective in their individual patients. Clinicians had quickly become aware that patients differed in terms of development of side-effects from medication, how the drugs were metabolised, how the drugs were absorbed or cleared from their body and how the drug–drug interactions affected drug levels in the individual patient's body. Adverse drug–drug interaction could lead to a failure of the drug combination to suppress HIV infections.<sup>54</sup>

**8.49** As noted in paragraph 8.9 above, the clinical manifestations of HIV infection are widespread: they can affect most organs of the body. In the early years of the epidemic, HIV-associated dementia and other significant neurological complications were serious and disabling consequences of HIV infection. It was therefore important to ensure that HIV drugs could get into the brain in sufficient volume so as to suppress HIV replication there. Similarly, the sexual transmission of HIV is thought to occur more readily if the amount of HIV is high in genital and rectal fluid. Therefore, choosing drugs which may achieve sufficient dilution in these fluids may reduce the risk of sexual transmission.<sup>55</sup>

### *The current situation*

**8.50** Currently, with almost 30 individual drugs from six drug classes to choose from, clinicians have considerable flexibility. Patients with HIV are well managed with these drugs and only a small number have run out of treatment options. At the present time, the majority of patients who are complying with treatment have fully suppressed HIV infection and those who are not controlling their virus almost always have adherence issues.

**8.51** Notwithstanding the increased range of drugs available, drug therapy does not cure people of HIV or AIDS: the virus is not completely eliminated from the body and starts replicating again if drug therapy is stopped.<sup>56</sup> Rather, the drugs suppress the virus, either by stopping the virus from replicating or by preventing it from binding to or entering human immune cells, or both.

**8.52** People undergoing treatment can still transmit the virus, however, and must continuously take antiretroviral drugs in order to maintain their health and to keep their infectivity suppressed. As noted in paragraph 8.22, there is currently no vaccine to prevent HIV infection nor is there a cure for HIV/AIDS. Professor Lever described the problem of developing a useable vaccine. Successful vaccines tend to replicate the natural immune response to infection: the vaccine triggers the same sort of immune response as does an individual who successfully clears the infection. He said:

The issue with HIV ... is that nobody who has been infected has ever developed an immune response which has cleared the virus from them completely. That's unique. And nobody has ever developed an immune response which completely protects them against a second infection. Both of those things relate, in part at least, to the fact that it is a very, very variable virus. It is not only that, because Hepatitis C is probably even more variable, but some people clear that.

It's also the fact that HIV integrates ... so it is difficult to find and eradicate.<sup>57</sup>

<sup>54</sup> Professor Leen – Day 33, page 48; Professor Leen's Report [PEN.012.1044] at 1053

<sup>55</sup> Professor Leen's Report [PEN.012.1044] at 1053 and 1054; Professor Leen – Day 33, pages 48–49

<sup>56</sup> Professor Leen – Day 33, page 50; Professor Leen's Report [PEN.012.1044] at 1054

<sup>57</sup> Professor Lever – Day 26, pages 148–9

**8.53** Professor Lever commented that the outlook for a protective vaccine was not good. Recent research suggested that a vaccine might conceivably be developed but that it would not be a conventional vaccine and would require regular administration.<sup>58</sup> By the close of the Oral Hearings of the Inquiry there remained uncertainty whether the reported research had progressed.

**8.54** Research continues in the area of gene therapy.<sup>59</sup> The discovery that the delta 32 mutation of the CCR5 protein on lymphocyte cells prevents infection with HIV<sup>60</sup> has led to the targeting of that particular protein as one of the suggested strategies for gene, as opposed to conventional drug-based, therapy.<sup>61</sup>

**8.55** Proof of concept of effective gene therapy has been provided in the case of Timothy Ray Brown (also known as 'the Berlin patient') who suffered from both leukaemia and HIV infection. It appears to be generally accepted that this recipient of a bone marrow transplant from a donor with both the same HLA type<sup>62</sup> and the CCR5 delta 32 mutation had the mutation passed on. Indications point to a functional cure.<sup>63</sup> However, the procedure – 'allogeneic haematopoietic stem cell transplantation' – is contra-indicated where the recipient does not have leukaemia (and, indeed, Brown experienced 'graft-versus-host' disease as a result of the transplantation). This isolated and quite exceptional case apart, effective gene therapy has not been developed to date.

### Morbidity and mortality

**8.56** Data for the impact of HIV/AIDS on NHS patients in Scotland receiving therapy for blood coagulation disorders and transfusions in the course of medical or surgical treatment are discussed in Chapter 3, *Statistics*. Mortality rates (reflecting the proportions of patients developing fatal conditions) were high and, among survivors, serious morbidity (reflecting severity of the illness) was very common. Very few indeed among those infected in the 1980s have had little serious ill health.

**8.57** In the UK as a whole, haemophilia patients were particularly severely affected. The United Kingdom Haemophilia Centre Doctors Organisation (UKHCDO) reported that in 2004, of a total population of 7250 male patients registered on the national database in 1985, 1246 (17.2%) were infected with HIV-1.<sup>64</sup> Among severely affected haemophilia patients, 65.8% of those with HIV had died between 1 January 1985 and 1 January 2000. The equivalent mortality for the mildly and moderately affected haemophilia patients with HIV was 59.9%.<sup>65</sup> Among the non-HIV-infected severely affected haemophilia patients alive in 1985, 18.3% had died by 1 January 2000 and 13.0% of the non-HIV-infected mildly and moderately affected patients had died by the same date. The difference in mortality between the infected and non-infected groups of patients appears to be largely attributable, directly or indirectly, to HIV/AIDS infection.

<sup>58</sup> Ibid pages 149–152

<sup>59</sup> That is, supplementing or directly modifying a patient's DNA as a pharmaceutical agent to treat disease.

<sup>60</sup> Professor Lever – Day 26, page 21

<sup>61</sup> Ibid page 20

<sup>62</sup> HLA types are discussed briefly in Chapter 13, *Knowledge of Viral Hepatitis Now*, paragraph 13.17

<sup>63</sup> Hutter et al, 'Long-Term Control of HIV by CCR5 delta 32/Delta 32 Stem-Cell Transplantation' *New England Journal of Medicine* 2009; 360(7):724–725 [LIT.001.5048]; Allers et al, 'Evidence for the cure of HIV infection by CCR5Δ32/Δ32 stem cell transplantation' *Blood* 2011; 117(10): 2791–2799 [LIT.001.4527]. (For an alternative view casting some doubt on the complete effectiveness of such a therapy, particularly in relation to 'T-cell reservoirs', see Nath et al, 'Eradication of HIV from the brain: reasons for pause' *AIDS* 2011; 25(5): 577–80 [LIT.001.4844])

<sup>64</sup> 'The impact of HIV on mortality rates in the complete UK haemophilia population'. *AIDS* 2004, 18:525–533; [LIT.001.1405]

<sup>65</sup> See Chapter 2, *Patients at Risk*, paragraphs 2.26–2.28 for a more technical discussion of the terms 'severely', 'moderately' and 'mildly' affected haemophilia patients.

**8.58** Among those infected, survival was strongly related to age at infection with HIV and the differences in mortality between HIV-infected and non-infected subjects were largely accounted for by HIV-related conditions. Without HIV infection, annual liver disease mortality (largely from HCV) remained below 0.2% throughout 1985–99. With co-infection (HIV plus HCV), liver disease mortality was 0.2% during 1985–90, and 0.8% during 1991–99. From 1997, after the introduction of effective treatment for HIV there were substantial reductions in annual mortality related to AIDS, though mortality from liver disease remained high. The risks in Scotland, as shown in Chapter 3, *Statistics*, were lower but still very significant.

### **Conclusion**

**8.59** It has to be emphasised again that the information about AIDS, its natural history and treatment, as discussed in this chapter, reflects the state of knowledge current at the close of the oral evidence heard by the Inquiry. Almost none of this would or could have been known before 1991. In particular, the understanding of clinicians and others at the time that patients were (often unbeknown) contracting HIV infection and suffering from AIDS-related conditions was very poor indeed in the first few years of the epidemic.

**8.60** Recognition of the new syndrome internationally and in Scotland; the emerging realisation that there was transmission by a blood-borne agent, posing risk to those undergoing blood transfusion or treatment with blood products; the identification of the virus; and the responses of scientists and clinicians to the threat posed to patients – the key issues identified in the Preliminary Report – remain for discussion in other parts of this Report (Chapters 9–12).

**8.61** However, the narrative of the current understanding of the natural history of HIV/AIDS takes on colour from the experiences of individuals exposed to the reality of the diseases. The impact on patients and their families is illustrated in the following chapters setting out the evidence provided to the Inquiry of their particular histories. The experiences described range between the extremes of patients who died of AIDS, either before effective drug therapy was available or notwithstanding therapy, and patients for whom treatment has been effective in arresting the progression of the disease. Some of the many witnesses who provided statements were invited to give oral evidence. The evidence of these witnesses, supplemented by the written accounts of others and, where possible and appropriate, by medical records, provides a telling picture of the wide impact of infection on the individuals affected and their families.

## CHAPTER 9

### KNOWLEDGE OF THE GEOGRAPHICAL SPREAD AND PREVALENCE OF HIV/AIDS 1

#### Introduction

**9.1** The impact of HIV/AIDS on National Health Service (NHS) patients receiving blood transfusions in the course of medical or surgical treatment or receiving blood, blood component or blood product therapy for coagulation disorders is part only of a much wider picture. The speed of response and the concentrated effort devoted first of all to understanding and then to dealing with AIDS, especially in the USA, reflected the apprehension that it was an epidemic threatening broad sectors of society.

**9.2** In a paper presented to a group of experts at the World Health Organization (WHO) on 14–16 April 1986, Dr John Ziegler, Director of AIDS Research at the American Veterans Administration Medical Center wrote:

The epidemic forces policy decisions in political, social, journalistic, and ethical spheres. The cause, prevention, and cure of AIDS has induced collaboration between clinicians, virologists, immunologists, molecular biologists, epidemiologists and sociologists. Thus this epidemic has, in five short years, mobilized a response from virtually every arena of human society.<sup>1</sup>

**9.3** In this chapter, the evolving picture will be examined from a narrow perspective, tracing developing knowledge of the incidence of diseases associated with HIV infection from the end of 1980, when cases of AIDS were first observed in the USA, to 1984, when testing for antibodies for HIV began to become available in the USA. This is with a view to providing context for the exploration of medical and scientific research into AIDS and the response to it, principally in the UK and the USA.

**9.4** However, it is appropriate also to take note, briefly, of the extent of the epidemic, particularly as it affected populations less able to respond to the challenges it presented, and still presents, than the cohorts with whom the Inquiry is particularly concerned.

#### A worldwide problem

**9.5** In 2006, the 25th anniversary of the emergence of AIDS in western countries, there were close to 40 million people around the world living with HIV infection and over 20 million people had died of HIV-related diseases. By 2009, the joint UNAIDS<sup>2</sup> and WHO publication *Global Facts and Figures* showed that since the beginning of the epidemic almost 60 million people had been infected with HIV and 25 million people had died.<sup>3</sup> By 2011, 30 years since HIV/AIDS was first discovered, 30 million people had died. The number of people living with the disease worldwide was estimated at 34.2 million, with a prevalence of 0.8% overall.<sup>4</sup> UNAIDS data showed wide variations in prevalence across regions, from 0.1% in East Asia to 5% in Sub-Saharan Africa. Western and central Europe were estimated to have 820,000 cases of infection, a prevalence of 0.2%. North America had 1.5 million cases, a prevalence of 0.5%.

<sup>1</sup> Ziegler, 'The Natural History of AIDS' in: Petricciani et al (eds), 1987, *The Safety of Blood and Blood Products in relation to AIDS*, The World Health Organisation: Tiptree, p.21 [LIT.001.5828]

<sup>2</sup> The Joint United Nations Programme on HIV/AIDS.

<sup>3</sup> UNAIDS/WHO *Global Facts and Figures* [LIT.001.5614]

<sup>4</sup> UNAIDS *Report on the Global AIDS Epidemic 2012* [LIT.001.5616]

**9.6** The epidemic in the UK, with particular reference to Scotland, is the context in which the Terms of Reference have to be addressed. Though a small part of the wider picture, it is not representative of it. The prevalence of the disease in the UK, and the response to it, has been materially different from the global picture. The emerging position in the USA usefully defines the wider context in which experience in the UK has to be seen. Along with other western countries, the USA and the UK have benefited from the investment of intellectual and financial resources not widely available in most areas with a high prevalence of infection.

**9.7** In the UK, AIDS surveillance began in 1982.<sup>5</sup> By the end of 2011, 120,756 people had been diagnosed with HIV, of whom 27,361 had developed AIDS and 20,335 had died.<sup>6</sup> The estimated prevalence of HIV in 2010 in the population of all ages was 0.15%: 0.18% in males and 0.09% in females. The Health Protection Agency (HPA) report for 2011 commented that the UK had a prevalence similar to other western European countries such as Ireland (0.2%), the Netherlands (0.2%) and Germany (0.1%), and lower than eastern and southern European countries such as Latvia (0.7%), Portugal (0.6%) and Spain (0.4%). Local social and environmental factors are reflected in those variations and, in geographical terms, a narrow field of study is required. However, it is not possible totally to isolate cases of infection in the UK from the wider world picture. A significant proportion of individuals diagnosed with HIV infection in the UK was originally infected abroad.<sup>7</sup>

**9.8** In the case of transfusion and blood disorder patients, experience was more clearly dependent on local factors: by definition NHS patients were treated in the UK. The risk of transmission of infection was related to the prevalence of infection in the donor population. Across western countries the picture varied. The prevalence of transfusion-transmitted AIDS in Australia was said in the mid-1980s to be 10 times greater than in the UK.<sup>8</sup> It was reported at that time that the prevalence of seropositivity<sup>9</sup> in the USA was 74% in people with Haemophilia A and 35% in people with Haemophilia B. In the USA, 15% of 'haemophilia wives' were seropositive, with the seroconversion rate still increasing.<sup>10</sup>

**9.9** By 1986, the Council of Europe had produced comparable data. For the UK, the data indicated positive findings in 896 (44%) of 2025 Haemophilia A patients tested and in 20 (6%) of 324 Haemophilia B patients tested. In severely affected Haemophilia A patients the proportion was 59%.<sup>11</sup> Comparative analysis of the widely divergent numerical data contained in these reports, even as between the USA and the UK, would not be helpful in tracing the history of the epidemic in Scotland.

**9.10** The numerical data on the prevalence of disease in Scotland are dealt with in Chapter 3, *Statistics*. The combined UK prevalence values are higher than comparable values for Scotland alone. The most up-to-date data available to the Inquiry indicate that for the UK, excluding Scotland, 1310 patients with bleeding disorders had tested positive for HIV by April 2012. Scotland has roughly 10% of the UK haemophilia population but

only 73 patients treated in Scotland tested positive, around 5% of the bleeding disorder patients infected with HIV.<sup>12</sup> Knowledge of these numbers would not emerge in the course of the period under discussion, 1981–1984.

## Origins of the disease

**9.11** AIDS was first reported in the USA in 1981. Data from the UK Haemophilia Centre Doctors' Organisation (UKHCDO) initially suggested that the first cases of HIV in haemophilia patients at Scottish centres were recorded retrospectively as having occurred in Aberdeen and Glasgow in 1982.<sup>13</sup> Earlier cases were identified and reported by Simon Garfield in his social history of HIV/AIDS, *The End of Innocence*.<sup>14</sup> The cases he noted appeared to demonstrate that AIDS was active in the USA and in the UK before 1981. Without verification, however, the reports gave no real insight into when AIDS first affected humans in western countries. It is clear, however, that none of these apparently isolated early cases was recognised or influenced medical and scientific thought when the first deaths in the modern epidemic came to light and were reported in 1981.

**9.12** Developments in the science of genetics and increasingly sophisticated technology applied to historic blood samples stored in the USA and the UK have now demonstrated that HIV infection had entered the population in the USA by 1978 and in the UK by 1979. Blood specimens retained from early studies of other conditions, and in particular Hepatitis B, were available for re-examination when appropriate technology was developed. Re-examination of specimens from a study of Hepatitis B infection in a cohort of homosexual men in San Francisco carried out between 1978 and 1984 disclosed HIV antibodies in samples dating from 1978.<sup>15</sup> Retrospective testing of samples from haemophilia patients in western Pennsylvania<sup>16</sup> and New York<sup>17</sup> also identified the first two cases of HIV seroconversion in that group of patients in samples from 1978. Similar testing in the UK has shown transmission of HIV to a haemophilia patient around June 1979.<sup>18</sup> Research into the origins of HIV continues.<sup>19</sup>

**9.13** The same technology has probably excluded one earlier date.<sup>20</sup> The death of a patient at the Manchester Royal Infirmary on 31 August 1959, aged 25, with a rare combination of symptoms, was reported in 1960 as a mystery.<sup>21</sup> In 1983 it was speculated that it might have been a case of AIDS.<sup>22</sup> In 1990, further study led to the conclusion that the patient

<sup>12</sup> Statistics – National Haemophilia Database – Bleeding disorder statistics for The Penrose Inquiry [PEN.019.0927] at 0961

<sup>13</sup> There is one unexplained retrospective test result from 1969 which appears to be unrelated to the events with which the Inquiry is concerned.

<sup>14</sup> The data are inconsistent and have not been verified. The 'Chronology of State Medicine etc' states that AIDS was first described in the USA in 1978. It also states that the first case of AIDS was reported in 1981: page 1, Introduction. Table 3, page 35, lists 'Cases of AIDS reported to the Regional Office of WHO as of 30 October 1983', and includes eight cases of AIDS in Europe before 1979, two cases in 1979, 10 cases in 1980 and 17 cases (including the first two cases in the UK) in 1981.

<sup>19</sup> In 2007, TP Gilbert and others published a study combining a range of phylogenetic, molecular, historical and epidemiological techniques, which traced the dispersal of HIV from Central Africa via Haiti to the USA, Europe (including the UK) and elsewhere. See Gilbert et al, 'The emergence of HIV/AIDS in the Americas and beyond', *Proceedings of the National Academy of Sciences*, 20 November 2007; Vol.104, No.47. [LIT.001.4483]. It is not necessary for present purposes to discuss these developments.

<sup>22</sup> Williams et al 'AIDS in 1959?' *The Lancet*, 1983; 322;1136 [LIT.001.5504]

had HIV infection.<sup>23</sup> In 1995, however, US researchers cast doubt on the previous findings and speculated that they might have been due to cross-contamination of samples.<sup>24</sup> Further studies followed.<sup>25</sup> The conclusion of the Manchester scientists involved – two of whom had contributed to the *Lancet* article in 1983 – was negative: they agreed that the 1959 patient did not carry HIV. For them the case had again become a mystery. The final contribution to date is from Professor Hamilton and Mr Hooper, Oxford, who in 1996 again expressed the belief that the patient did not have AIDS.<sup>26</sup> The debate so far suggests that the case is not an early example of HIV infection, notwithstanding that the patient had signs and symptoms of diseases of the AIDS complex at his death. It illustrates the role of technology in developing understanding of the epidemiology of the disease and in particular the late date at which a measure of confidence in diagnosis was achieved.

**9.14** It can be said with greater confidence that knowledge of the emerging epidemic was disseminated first in 1981, with a great deal of literature published in and after June of that year. From the first clinical descriptions of the disease, concern began to grow. As seen from the perspective of staff at the Regional Haemophilia Centre, Glasgow Royal Infirmary (GRI), commenting on the early reports:

It was soon apparent that these cases represented the first reports of a new epidemic, one which medicine had not seen before, and one which has had dramatic consequences scientifically, medically and socially.<sup>27</sup>

**9.15** Within the UK, scientific and medical literature initially dealt mainly with experience in the USA and the literature most widely available to British scientists and doctors was published first in the USA and only later in the UK.

**9.16** In order for the Inquiry properly to understand the response to the epidemic as it affected those who received transfusions of blood and blood components and blood product therapy, it was necessary to trace the origins of the AIDS epidemic, and the publicity that it attracted, at least to the USA, and to place in context the emerging understanding of its impact on haemophilia and other patients. Knowledge of the groups at risk of infection quickly became widespread, while knowledge of the prevalence and natural history of AIDS-associated disease developed more slowly. The Preliminary Report set out much of the information recovered in chronological form and will not be repeated in detail.<sup>28</sup>

### **Early reports of infection in the United States of America: 1981–1982**

**9.17** Early reports in the USA presented a picture of rapidly increasing numbers of patients with perplexing signs and symptoms with high mortality and unknown cause. In *The Tragic History of AIDS in the Hemophilia Population 1982 – 1984*, Dr Bruce Evatt of the US Centers for Disease Control (CDC) wrote:

First apparent in the homosexual population in the USA in the last quarter of 1980, the disease possessed unusual properties that initially obscured

it as a distinct infectious disease. Previously healthy victims had no specific symptoms but presented with either secondary infections or tumors associated with immune deficiency (i.e. *Pneumocystis carinii* pneumonia (PCP) or Kaposi's sarcoma)<sup>29</sup>. A long incubation time made it difficult to identify person-to-person spread. Laboratory methods needed to culture and identify the etiologic agent were lacking.<sup>30</sup>

### ***First reports: the association with sexual behaviour***

**9.18** The first US reports of AIDS created, for a time, an impression that the disease was a purely US phenomenon associated with sexual behaviour. The published history begins in 1981 when physicians in New York, Los Angeles and San Francisco reported previously healthy homosexual men with *Pneumocystis carinii* pneumonia (PCP). The Los Angeles cases were described in the *Morbidity and Mortality Weekly Report (MMWR)* for 5 June 1981.<sup>31</sup> That report is generally regarded as the first published recognition by a public health body of what was to become characterised in the 1980s as 'the AIDS epidemic'. Additional reports soon followed. Apart from the unusual nature of their illnesses, there was no common characteristic other than homosexual activity and in that respect the patients did not have a history of association with each other. As at 1981, the existence of what came to be known as AIDS was inferred from the constellation of very unusual tumours, such as Kaposi's sarcoma (KS), and other clinical signs and symptoms, including PCP, in patients who died fairly quickly after initial diagnosis.

**9.19** Kaposi's sarcoma in young homosexual men was brought to the notice of doctors in the UK in *The Lancet* of 19 September 1981 but it was reported as a US phenomenon.<sup>32</sup>

### ***A widening constituency: intravenous drug use***

**9.20** The range of people known to be at risk was extended when, on 10 December 1981, the *New England Journal of Medicine (NEJM)* reported PCP in seven intravenous drug users (IVDUs), only two of whom were homosexuals. It was suggested that IVDUs and homosexuals were at high risk for PCP but there was still an emphasis on male homosexuals as people particularly at risk.<sup>33</sup> At the time, the term 'Gay Compromise Syndrome' was coined for the 'newly recognised syndrome of opportunistic infections and/or KS in homosexual males'.<sup>34</sup>

**9.21** In terms of published intelligence, at the end of 1981 and continuing into 1982, reports in the *NEJM*, *The Lancet* and the *British Medical Journal (BMJ)* added to general knowledge that IVDUs were affected in addition to members of the male homosexual population.

<sup>29</sup> These diseases were known, but extremely rare and, outwith specific ethnic groups in the case of KS, usually only presented in immuno-compromised patients.

<sup>30</sup> Evatt, 'The tragic history of AIDS in the haemophilia population, 1982–84', *Journal of Thrombosis and Haemostasis*, 2006; 4/11:2295–2301 [PEN.016.1183] at 1185

<sup>31</sup> '*Pneumocystis* Pneumonia – Los Angeles', *Morbidity and Mortality Weekly Report*, 1981; 30: 250–2 [LIT.001.1026]. *MMWR* is published by the Centers for Disease Control and Prevention (CDC), a US government public health agency with its headquarters in Atlanta, Georgia. It is a publication which the Protein Fractionation Centre (PFC) in Edinburgh received; Preliminary Report, para 8.4. ### *A widening constituency: haemophilia patients*

**9.22** The earliest case of AIDS-related disease in a haemophilia patient, so far as is known to the Inquiry, was identified in October 1981. The case was not fully reported until February 1983 but the circumstances of a patient discussed by Professor Oscar Ratnoff of Cleveland, Ohio (one of the authors of the later report on the case) and Professor Charles Forbes, Director of the Regional Haemophilia Centre, Glasgow, at the end of 1981 were probably related to it.<sup>35</sup> Professor Ratnoff told Professor Forbes of haemophilia patients who were clearly ill with various opportunistic infections and tumours and of a patient of his who had a ‘funny immune problem in his blood’ and was obviously ill and eventually died.<sup>36</sup> He asked whether Professor Forbes had seen such cases (he had not, at the time). Thus at least one haemophilia clinician in Scotland had personal notice of the emerging problem, beyond the sexual context, from this time.

### *The first year*

**9.23** By June 1982, a year after the first report of AIDS, KS and opportunistic infections had been reported in 355 relevant cases in the USA.<sup>37</sup> The majority of the individuals infected (79%) were homosexual or bisexual men; 11% were heterosexual men; 4% were heterosexual women; and 6% were men of unknown sexual orientation. It was suggested that all of the cases were part of the same epidemic.

**9.24** In light of the oral evidence heard by the Inquiry, it would be wrong to imagine that the published reports communicated a clear account of the developing picture to the medical community generally. Across the professions experience was patchy: the patients were widely spread and few doctors would have had direct experience. Professor Andrew Lever, Professor of Infectious Diseases at Addenbrooke’s Hospital, Cambridge, distinguished those with direct experience, doctors looking after patients suffering from these infections and specialists such as epidemiologists with a specific interest, from clinicians generally. Individual physicians managing patients with AIDS and epidemiologists would have been trying to work out what was going on.<sup>38</sup> Professor Lever explained:

Mostly the people who saw the initial cases were seeing a lot of [them] ... or at least several, and it would have been an unusual phenomenon for anyone to have seen one of these and certainly very unusual for them to see two or three.<sup>39</sup>

**9.25** Experience was concentrated in a relatively small cohort of specialist practitioners. For most clinicians the published reports and comments would have described events of which they had no personal knowledge or experience. In the UK medical community, the impression was created, and persisted, that the disease was a US phenomenon.

### *The second year*

**9.26** Experience of AIDS was beginning to spread internationally, however. The cases of four Danish men who had developed KS or opportunistic infections were reported in July

<sup>35</sup> Professor Forbes – Day 17, pages 92–93; Professor Forbes’ Witness Statement [PEN.015.0254] at 0256. Professor Forbes’ recollection that this occurred in 1980 cannot be correct. The telephone conversation referred to must have been a year later.

<sup>38</sup> Day 26, pages 37–38

<sup>39</sup> *Ibid* page 38

1982.<sup>40</sup> It was apparent that the syndrome was occurring in homosexual men in Europe as well as in the USA.

**9.27** In the same month, opportunistic infections among Haitian immigrants to the USA were reported.<sup>41</sup> At that time, the explanation for a concentration of cases in Haiti had not been documented and there was not a very clear idea about how the disease had arrived there.<sup>42</sup>

**9.28** On 16 July 1982, the *MMWR* reported three cases of PCP in haemophilia patients.<sup>43</sup> All were heterosexual males with no history of intravenous drug use. Two had died and one was critically ill. All had lymphopenia (abnormally low levels of lymphocytes, white blood cells important to the immune system) and the two who had been specifically tested had *in vitro* laboratory evidence of cellular immune deficiency. There had been a further material change in context moving away from an exclusive focus on the sexual behaviour of male homosexuals.

**9.29** By July 1982, the US Centers for Disease Control (CDC), and Dr Evatt in particular, were convinced by evidence of infection in haemophilia patients that AIDS was a blood-borne disease, though there was no direct proof. It is important to bear in mind, however, that there was no consensus at this stage that AIDS was even an infectious disease.

**9.30** In September 1982, it was reported again that intravenous drug use was a risk factor.<sup>44</sup> An update in the 'Current Trends' section of the *MMWR* stated that the incidence of AIDS had roughly doubled every half year since the second half of 1979. Among the 14 cases involving males under the age of 60 who were not homosexuals, IVDUs or Haitians, two (14%) had Haemophilia A. It was suspected that the eventual mortality rate of AIDS might be far greater than the overall 41% case-mortality rate noted for the total of 593 cases identified at that point. The editorial note suggested that Haemophilia A was perhaps a risk factor.

**9.31** There were further significant reports in the *MMWR* of 10 December 1982 of four more cases in the USA of heterosexual Haemophilia A patients with opportunistic infections, one suspected case in a 7 year old haemophilia patient and a report of a possible transfusion-related case of AIDS in a 20 month old child from San Francisco.<sup>45</sup> The editorial comment on the group of four patients stated:

These additional cases provide important perspectives on AIDS in U.S. hemophiliacs. Two of the patients described here are 10 years of age or less, and children with hemophilia must now be considered at risk for the disease. In addition, the number of cases continues to increase, and the illness may pose a significant risk for patients with hemophilia.<sup>46</sup>

<sup>46</sup> *Ibid* [SGH.008.5105] at 5108

**9.32** The infant from San Francisco had received multiple transfusions which had included platelets from a male found to have subsequently developed AIDS. The editorial note stated that several features of the infant's illness resembled those seen among adults with AIDS but warned that, since there was no definitive laboratory test for AIDS, any interpretation of the child's illness would need to be made with caution. It proceeded:

If the platelet transfusion contained an etiologic agent for AIDS, one must assume that the agent can be present in the blood of a donor before onset of symptomatic illness and that the incubation period for such illness can be relatively long ....

....

This report and continuing reports of AIDS among persons with hemophilia A raise serious questions about the possible transmission of AIDS through blood and blood products....<sup>47</sup>

**9.33** Discussion of the case of the infant at the Inquiry's Oral Hearings disclosed varying opinions of its significance: see Chapter 11, *AIDS Aetiology*, paragraphs 11.24–11.27.

**9.34** The initial reports of infections in homosexual men had left medical scientists in the USA unclear how the clustering of KS, PCP and other opportunistic infections were related. Over a short period of about 18 months, however, by autumn of 1982 thinking had moved on to the definition of a condition with specific signs and symptoms and identified groups at risk. People at risk in the USA included homosexual and bisexual men, IVUDs, heterosexual haemophilia patients, immigrants from Haiti and, more rarely, other heterosexual males and females without known risk factors.

### Response in the United Kingdom 1981–1982

**9.35** It should not be thought that the early US publications were immediately available in a practical sense, at or about the dates of their issue, to all clinicians and other doctors who would come to have an interest in the subject. The *MMWR* was a publication of particular interest to infectious diseases specialists. It was not likely to be widely read in ordinary course by many clinicians in the UK and, before AIDS became a matter of general interest, haemophilia clinicians and transfusion doctors (whether in the USA or in the UK) would not have been regular readers of the publication.<sup>48</sup> The early stages of the AIDS outbreak in the USA would have been known to some infectious diseases specialists from reading and soon from direct contact with patients or from discussion.<sup>49</sup> Haemophilia doctors also became aware of AIDS relatively quickly.

**9.36** The HPA 2011 Report, *HIV in the United Kingdom*, noted the first reports of AIDS in Los Angeles of 5 June 1981 and commented:

Ten days later, the first UK case of AIDS was reported in a young man with haemophilia followed by further reports of AIDS among homosexual men. These first reports prompted the creation of the UK's AIDS surveillance scheme in 1982.<sup>50</sup>

<sup>47</sup> 'Possible transfusion-associated acquired immune deficiency syndrome [AIDS] – California', *Morbidity and Mortality Weekly Report*, 1982; 31:652–654 [SGH.008.5105] at 5109–10

<sup>48</sup> Professor Ludlam – Day 18, page 95. See also: Dr Foster – Day 23, pages 6–7; Dr Foster's Witness Statement [PEN.015.0101] at 0107

<sup>49</sup> Professor Lever – Day 26, page 73

<sup>50</sup> HPA HIV in the United Kingdom: 2011 Report [LIT.001.4443] at 4448.

**9.37** The Inquiry's investigations have disclosed that the HPA Report, which was reviewed in January 2011 and again in November 2012, is inaccurate in this respect: there was no report of AIDS in a young haemophilia patient in the UK in June 1981. Public Health England, the successor to the HPA, has explained that the HPA confused the date of a sample from 1981, which was tested retrospectively when a haemophilia patient in Scotland was first diagnosed with clinical AIDS in 1994, with the date of first diagnosis.<sup>51</sup> The first reported case of clinical AIDS in the UK was the case of 'the Brompton patient'. *The Lancet* of 12 December 1981 published details of a 49 year old homosexual man (a frequent visitor to Florida), who had reported to Brompton Hospital. He was diagnosed with PCP and cytomegalovirus (CMV) but had no underlying immune deficiency.<sup>52</sup> Information was now circulating about AIDS in a UK patient, albeit one with US and homosexual associations.

**9.38** The Inquiry had the benefit of written and oral evidence from Dr Mark Winter, who became Consultant Haematologist at Kent and Canterbury Hospital in 1983. Dr Winter was a Senior Registrar at Guy's Hospital at the time of the Brompton Hospital case in 1981 and the topic was widely discussed among his colleagues.<sup>53</sup> Professor Lever was working with Dr David Webster at Northwick Park Hospital at the time. Although Professor Lever could not be certain, it appears highly likely that the patient from Brompton Hospital was transferred to Dr Webster's care and that he was one of the first two AIDS patients seen by Professor Lever in 1981–82. The second was a child recently arrived from the southern USA or the Caribbean.<sup>54</sup> The information given to Professor Forbes of Glasgow at the end of 1981 by Professor Ratnoff of what was probably the earliest case of AIDS-related disease in a (US) haemophilia patient known to a UK practitioner has already been mentioned in paragraph 9.22. A few doctors in the UK derived knowledge of the condition from direct contact with patients and from discussion with colleagues at the initial stages of the outbreak. As previously noted, surveillance of AIDS-related disease in the UK began in 1982.

**9.39** By the end of 1981, no cases had been seen in Scotland. Professor Forbes had received personal communication from Professor Ratnoff, and Professor Christopher Ludlam (Director of the Edinburgh Haemophilia Centre) was familiar with the literature.<sup>55</sup> It is not clear, however, how widely the emerging epidemic was known or studied at this point by Scottish haemophilia clinicians or other practitioners concerned with the use of blood, blood components or blood products. Early surveillance is more likely to have engaged physicians concerned with the diagnosis and treatment of AIDS-related diseases such as infectious diseases doctors, cardiologists, respiratory specialists and cancer doctors.

### *The Second International Symposium on Infections in the Immunocompromised Host*

**9.40** Information about the emerging epidemic was disseminated by a number of professional groups but not always shared on an interdisciplinary basis. In June 1982, the Second International Symposium on Infections in the Immunocompromised Host was held in Stirling. Professor Ian Hann, then at the Royal Free Hospital, London, but soon

<sup>51</sup> There were samples from Edinburgh (Chapter 3, *Statistics*, Table 3.16, case E22); the GRI (Chapter 3, *Statistics*, table 3.17, case G12) and Yorkhill (Chapter 3, *Statistics*, table 3.18, cases Y2, Y5 and Y14) taken in 1981 which subsequently proved positive for HIV antibodies on retrospective testing. None of these were known in 1981 or 1982 and they could not have prompted HIV/AIDS surveillance measures in 1982.

<sup>52</sup> Du Bois et al, 'Primary Pneumocystis Carinii and Cytomegalovirus infections', *The Lancet*, 12 December 1981; 1339 [LIT.001.0399]. So far as the Inquiry's investigations have disclosed, this was the first published reference to the syndrome in a British patient.

<sup>53</sup> Day 15, pages 110–111

<sup>54</sup> Professor Lever – Day 26, pages 73–74

<sup>55</sup> Day 18, page 91

to move to The Royal Hospital for Sick Children, Yorkhill, Glasgow (Yorkhill), attended.<sup>56</sup> One of his main interests at the time was infections in patients who had either immune deficiencies or, more commonly, leukaemia and cancers which made them very susceptible to infection. The symposium was to become the main regular meeting in the world of specialists dealing with such infections.<sup>57</sup> However at the time of the second meeting, it is unlikely that specialists in other fields were aware of its existence. Apart from Professor Hann, none of the haemophilia clinicians who gave evidence to the Inquiry attended the meeting or knew about it.<sup>58</sup> This provides a clear example of one of the consequences of professional demarcation: there is no evidence that information from the symposium was communicated by those attending to colleagues with different specialist interests.

**9.41** In relation to widening knowledge of AIDS in the UK, the timing of the meeting is instructive. AIDS was not on the programme for the Stirling symposium as originally prepared. The topic of AIDS in homosexuals and drug addicts came to the fore later and a special lecture, 'Acquired Immuno-Deficiency Syndrome: infection and neoplasia in homosexual men and intravenous drug addicts', was added.<sup>59</sup> The opening passage of the paper referred to experience in the USA and stated:

We are experiencing an alarming epidemic of an acquired immunodeficiency syndrome (AIDS) in certain cities in the United States. It is affecting homosexual men, intravenous drug abusers of either sex and Haitian refugees ....

We are seeing such cases on a regular basis in New York City .... AIDS patients are regularly seen in Los Angeles, San Francisco and other large cities in the United States and cases have also been reported from Europe.<sup>60</sup>

**9.42** At the symposium, AIDS patients were reported to have developed opportunistic infections, KS and other malignancies.<sup>61</sup> A high mortality rate was reported: 13 of 42 patients in New York had already died. PCP in particular was associated with high mortality. It was noted that those who took care of the patients realised how devastating this illness was.

**9.43** The paper did not mention haemophilia patients as being at risk. Professor Hann recollected, however, that there was a 'corridor discussion' of other possible groups of affected patients including a very small number with haemophilia.<sup>62</sup> The authors of the paper on AIDS were mainly from New York but also included Dr James Curran and others from CDC, Atlanta, who may have known of Dr Evatt's views (described in paragraph 9.29 above). Professor Hann's evidence is particularly telling. He remembered the meeting well as it was so shocking. At the time of the symposium, his interests did not include haemophilia and the 'corridor discussion' left him with the impression, as he moved into haemophilia care at Yorkhill at the beginning of 1983, that AIDS might possibly be relevant to his haemophilia patients; but, he said, AIDS was perceived at the time to be mainly a problem of sexual transmission and possibly also of intravenous drug use.<sup>63</sup>

### *Official reaction*

**9.44** In UK government circles, the emerging problem was noted. On 16 July 1982, an internal Department of Health and Social Security (DHSS) memorandum advised that information had been received from the USA concerning the safety of US Factor VIII. The author of the memorandum (name redacted but probably written by a middle ranking official in the Department to another official who was medically qualified) stated that research was about to be published indicating that plasma taken from homosexual drug users contained a sort of virus and that, when the plasma was used for the production of Factor VIII, the virus could be passed on to haemophilia patients. It was claimed that '400 haemophilia patients in the USA [had] exhibited signs of the virus.' The memorandum noted that, with the UK's voluntary unpaid donor system, there was not the same problem of drug addicts being tempted to give blood for money. The author also noted, however, that about half of the concentrate used in the UK at this time was imported commercially from the USA.<sup>64</sup>

**9.45** In fact, up to the end of 1982, there was limited use of commercial concentrates by haemophilia centres in Scotland, with the exception of Yorkhill. Otherwise, the west of Scotland and the Edinburgh and east of Scotland centres used some commercial concentrates but mainly used Scottish concentrates or locally produced cryoprecipitate.<sup>65</sup> It is quite unclear where the 'information received from America' came from and the Inquiry has found no evidence to support the statement (from July 1982) that 400 haemophilia patients in the USA had exhibited signs of this virus. In fact, by coincidence, also on 16 July 1982 the *MMWR* published an account of the first three haemophilia patients in the USA thought to have AIDS.<sup>66</sup>

**9.46** In the UK, the Haemophilia Centre Directors began exploring the issue of AIDS in the autumn of 1982, remitting to Dr John Craske, who represented the Public Health Laboratory Service (PHLS), Withington Hospital, Manchester, the task of looking into the report from the USA of the syndrome in homosexual men and recently reported in three haemophilia patients. At that stage, the impression reflected in the minutes of the Directors' meeting of 13 September was that '[i]t appeared that there was a remote possibility that commercial blood products had been involved.'<sup>67</sup>

**9.47** Dr Frank Boulton, Deputy Director of the Edinburgh Blood Transfusion Centre, prepared a note of the Directors' meeting. In relation to AIDS, he stated:

This is a wasting disease with deficient cell-mediated immunity, possibly associated with an infectious element ....

Mortality 40-50%.

Three cases have occurred in haemophiliacs in the USA, possibly associated with parenteral drug abuse.<sup>68</sup>

<sup>64</sup> Memorandum [DHF.001.6744].

<sup>68</sup> Note of the Director's meeting [SNB.001.7494] at 7502

**9.48** Dr Boulton emphasised that the note did not express his personal opinion. He could not recollect who had suggested the association with 'parenteral drug abuse'.<sup>69</sup>

**9.49** Dr Winter was asked by the Inquiry about the reference to drug use in Dr Boulton's note; an association with drug use had not been mentioned in the *MMWR* of July. Dr Winter thought that there was a feeling at this time that only three haemophilia patients were affected, in the USA, and it was not absolutely certain that they were not part of some other risk group. He advised that a lot of attention was being paid to Germany where 'spectacularly high' quantities of imported Factor VIII were used. He said:

I think in fact the Bonn centre one year used more than every American centre put together, and one of the things that was said regularly at this time was, "If this is a new disease and it is in blood, why aren't the Germans getting it because, if anybody is going to get it, the Germans will."<sup>70</sup>

**9.50** Dr Craske asked the Directors to let him know if they had any cases of the syndrome. It was noted that the Hepatitis Working Party was considering the implications of the reports from the USA.<sup>71</sup> The Hepatitis Working Party was a UKHCDO group but had a wider membership than Haemophilia Centre Directors exclusively. Dr Craske was to have a pivotal role in collecting and disseminating intelligence on the disease among UK clinicians and scientists. Study of the prevalence of AIDS in the UK haemophilia population had begun but, subject to the 'remote possibility' that commercial blood products were implicated (a factor which would have had relevance in the UK generally but in England and Wales in particular), it was viewed as primarily a US problem at that stage and few haemophilia patients in the USA were affected. Professor Ludlam thought that the explanation for the assessment of risk as relatively low was that three only out of 20,000 haemophilia patients in the USA had been reported as being infected.<sup>72</sup>

**9.51** There was still a lack of communication of emerging knowledge among different professional groups in Scotland. As noted in the Preliminary Report, the minutes of the meetings of SNBTS Directors for 1982 did not disclose discussion of AIDS by Transfusion Directors at any meeting during the year.<sup>73</sup>

**9.52** At the end of 1982, therefore, there was emerging interest in the UK in AIDS but there was no general understanding that AIDS was a problem for Scotland or for any particular cohort or cohorts of potential patients.

### **Developments in the United States of America: 1983–1984**

**9.53** On 21 January 1983, an article in *Science* (published in the USA but one of the most widely-read and most prestigious science publications in the world) described a recent CDC workshop on the new immune disease.<sup>74</sup> Among topics discussed was the possibility that the disease might be spread through blood and blood products. The CDC had reported that haemophilia patients were at high risk of contracting AIDS. Dr Evatt, CDC, told the workshop that AIDS was the second leading cause of death for haemophilia patients in 1982.

<sup>74</sup> 'Health Officials Seek Ways to Halt AIDS', *Science*, 1983; 219:271–272; [LIT.001.1589]

**9.54** A widening range of people at risk was reported in the USA in 1983 and 1984. In January 1983 two cases of AIDS in the female sexual partners of IVDUs were reported.<sup>75</sup> Reports of infection in the Cleveland Hemophilia Center and other centres were published in the *NEJM* in February 1983.<sup>76</sup> All of the patients had a disorder resembling idiopathic thrombocytopenic purpura (a recognised autoimmune condition characterised by abnormally low platelet counts). Three out of four of the patients studied in 1981 and 1982 demonstrated evidence of impaired cell-mediated immunity. It appears highly likely that one of these was the patient discussed by Professors Ratnoff and Forbes at the end of 1981. Further cases of AIDS in haemophilia patients in the USA were reported in March 1983.<sup>77</sup> At the same time there were additional reports of immune abnormalities in young haemophilia patients who were otherwise apparently well.<sup>78</sup> An editorial in *The Lancet* for 2 April 1983 referred to reports from the USA of haemophilia patients, who had received Factor VIII concentrates, developing AIDS.<sup>79</sup> On 30 April, letters in *The Lancet* reported AIDS in 11 haemophilia patients in the USA and three in Spain who had received commercial concentrate.<sup>80</sup>

**9.55** A leaflet entitled *Facts about AIDS* was published by the US Public Health Service in September 1983.<sup>81</sup> The opening paragraph advised that AIDS was the number one priority of the US Public Health Service. Since 1981 the service had received reports of more than 2200 cases with a mortality rate of almost 40%. The leaflet included information about the nature and extent of AIDS, identifying who was at risk and giving advice on preventative measures. In the paragraph headed 'What causes AIDS?', it stated: 'The best evidence for transmission of AIDS through blood products is the occurrence of AIDS in a small number of hemophilia patients receiving large amounts of Factor VIII, a clotting substance in blood.' The leaflet included a number for a toll-free AIDS hotline where up-to-date information could be obtained.

### *Joint meeting of the World Federation of Hemophilia and the International Society for Thrombosis and Haemostasis*

**9.56** Dr Evatt reached a wide audience for his views at a joint meeting of the World Federation of Hemophilia and the International Society for Thrombosis and Haemostasis, held in Stockholm in June 1983. He reported that, by that date, the total number of confirmed AIDS cases in the USA was marginally higher than would be predicted from an exponential growth of the disease.<sup>82</sup> Haemophilia patients were in the group of infected people who developed opportunistic infections and there were 16 confirmed haemophilia patient cases in the USA (with eight dead by that date), three in Spain, one in Wales and one in Canada. Other delegates at the conference commented that there were more cases than that outside the USA (in Canada, Germany, Israel and Sweden) and that it was possible that these had not been confirmed by the CDC by that date. Of the 16 US haemophilia cases, one related to a mildly affected Haemophilia B patient.

<sup>81</sup> Information leaflet [DHF.001.4724]

<sup>82</sup> Dr Foster's report of the meeting dated 15 July 1983 [SNF.001.3712]

**9.57** Further data on the developing picture worldwide was provided at a WHO conference held in Geneva in November 1983.<sup>83</sup> It was reported that it had been recognised by then that the cases already diagnosed had involved infection as early as 1978, implying a much longer incubation period before the appearance of significant disease than had previously been assumed. The fatality rate was high – less than 20% of those with AIDS were alive two years after diagnosis.<sup>84</sup>

**9.58** Data were updated to 5 December 1983 in the draft report of the conference.<sup>85</sup> AIDS cases in the USA reported to the CDC by that date were:

**Table 9.1: Patients at Risk, December 1983**

Patients at Risk	Cases	Males	Females
Homosexual or Bisexual	2052	2052	
Intravenous Drug Users	490	387	103
Others	326	240	86
<b>Total</b>	<b>2868</b>	<b>2679</b>	<b>189</b>

**9.59** In the USA, 0.7% of cases were in people with haemophilia and no other known risk factor and 1% of cases were in those who had received a blood transfusion in the previous five years.<sup>86</sup> There were, in addition, paediatric cases linked with blood transfusion in which sexual transmission could be ruled out.<sup>87</sup> The cases diagnosed were concentrated in five urban areas of the country.<sup>88</sup>

**9.60** The major part of the report dealt with surveillance, prevention and control of the disease. By this point there was no question that the USA was confronting a disease of epidemic proportions. Significantly, the draft report of the conference noted that the emerging epidemiological patterns in most western European countries were very similar to the pattern then established in the USA.

### *Further developments*

**9.61** The *MMWR* of 2 December 1983 noted that, based on CDC advice, as at 30 November 1983, 21 cases of AIDS had been reported among haemophilia patients in the USA, 19 among patients with Haemophilia A and 2 among patients with Haemophilia B. In addition, 7 cases from outside the USA had been brought to the attention of the CDC.<sup>89</sup>

**9.62** The retrospective studies referred to above (paragraphs 9.11–9.12), which were carried out on stored frozen blood samples of haemophilia patients using HTLV-III/HIV antibody assays, were enabled by the isolation and characterisation of the AIDS retrovirus in 1983 and 1984 and the development of antibody tests in and after 1984.<sup>90</sup> These revealed that,

Chapter 29, *The Discovery of HIV and the Development of Screening Tests*, deals more extensively with the discovery of HIV.

in the USA, the peak in haemophilia patient seroconversion occurred in 1982 and 1983, with the earliest known seroconversions in 1978, shortly before the AIDS epidemic among homosexual men and intravenous drug users was first reported. By the end of 1983 and into 1984 the trends were becoming well established.

**9.63** Experience of AIDS in the USA had been discussed at a conference of combined clinical staffs at the US National Institutes of Health (NIH) Clinical Research Center, Bethesda, Maryland, on 23 June 1983. An edited summary of the proceedings was published in the *Annals of Internal Medicine* dated 1 January 1984, giving wide publicity to the discussion. The article observed that there had been a doubling of the number of patients afflicted every six months since the original reports in June and July 1981. It proceeded:

Because the incubation period for adults is generally felt to be greater than 1 year, the full scope of the syndrome has not yet been realized. However, the syndrome's pattern of transmissibility suggests that it will remain largely confined to the groups already affected, with minor intrusions into other populations not at high risk.<sup>91</sup>

**9.64** Four major risk groups were identified: homosexual and bisexual men; IVUDs with no history of homosexual activity; Haitian immigrants; and persons with haemophilia. A fifth group (3.8% of reported cases) comprised cases where no association was apparent or known. While numbers of individuals infected would continue to grow, the focus changed from reporting the prevalence of AIDS to the identification of the virus and then to tests for infection and to treatment.

**9.65** In relation to haemophilia patients, the situation was developing quickly. In July 1984, the first experimental antibody tests for the newly confirmed HIV became available in the USA. On 26 October 1984, the US CDC published an update on AIDS in people with haemophilia.<sup>92</sup> A total of 52 cases had been reported of haemophilia-associated AIDS in the USA. Thirty patients had died and only three diagnosed more than a year previously were still alive. The CDC had studied over 200 recipients of Factor VIII and 36 recipients of Factor IX concentrates containing materials from US donors. AIDS virus antibody rates of prevalence were 74% for Factor VIII recipients and 39% for Factor IX recipients.

**9.66** On 31 October 1984, Professor Elaine Eyster at the Milton S Hershey Medical Center, Pennsylvania State University, wrote to Dr Brian McClelland, Director of the Edinburgh Blood Transfusion Service, about work carried out by her team:

The data on sero conversion rates in 30 patients has not yet been put into abstract form or submitted for publication. I can tell you, however, that sero conversion began in 1979 when three of the 30 patients tested in 1983-84 became positive. The number steadily increased, with the big jump occurring in the year 1982.<sup>93</sup>

**9.67** Retrospective testing of stored serum samples was adding to the available knowledge of the history of transmission of infection.<sup>94</sup>

<sup>91</sup> Fauci *et al*, 'Acquired immunodeficiency syndrome: epidemiologic, clinical, immunologic, and therapeutic considerations', *Annals of Internal Medicine*, 1984; 100:92-106 [LIT.001.1573]

<sup>92</sup> 'Update: Acquired Immunodeficiency Syndrome (AIDS) in Persons with Hemophilia', *Morbidity and Mortality Weekly Report*, 1984; 33/42:589-91 [LIT.001.0460]

<sup>93</sup> Professor Eyster's letter to Dr McClelland [SNF.001.2512]

<sup>94</sup> Dr McClelland's reply 13 November 1984 [SNB.006.5999]

**9.68** By the end of 1984, the epidemic was well established in the USA, generally and in relation to haemophilia patients. The numbers of individuals infected were an indication of its extent but they were no longer relevant to whether there was a disease, or to diagnosis, or to treatment.

### Reports from outside the United States of America

**9.69** In the UK, the emerging epidemic was brought to the notice of the general public in media comment. An article published in *The Observer* in January 1983 entitled 'Mystery disease threat' stated: 'A commercial blood product imported into Britain from the United States may pose a grave threat to the health of haemophiliacs who inject it to encourage clotting'.<sup>95</sup> The article continued by saying that the product, Factor VIII concentrate, was being linked in the USA with a devastating new disease which caused a serious breakdown in the body's immune system. It was noted that the spread of the disease was described by officials at the CDC as 'an impending epidemic' among haemophilia patients. The article went on to describe how the disease had advanced from the homosexual community to include haemophilia patients.

**9.70** Data were made known to a significant number of UK doctors when Dr Craske's research up to the end of 1982 was reported informally on 24 January 1983 at a meeting held at Heathrow Airport chaired by Professor Arthur Bloom.<sup>96</sup> The report dealt mainly with experience in the USA. Dr Craske reported that the population groups affected by AIDS in the USA included promiscuous homosexuals, heroin addicts, immigrants into the USA from Haiti and haemophilia patients. Up to 10 December 1982, some 800 people had been reported as suffering from AIDS and there was a 45% mortality rate. Ten haemophilia patients in the USA had been affected, including a 7 year old child, and five had died. By that stage, only one or two cases of AIDS had been reported from the Communicable Disease Surveillance Centre (CDSC), based in Colindale, London.<sup>97</sup>

**9.71** Dr Craske's report would have provided important and well researched information to those attending the meeting. In the case of the US haemophilia patients, all had prolonged treatment with Factor VIII but there was no implication of one particular product or batch. It would have been clear that the problem was not limited to a single production process or event. Cases involving blood and blood product transmission had included platelet transfusions. An association with transfusion was explicit in some of the cases.

**9.72** Lack of understanding of the natural history of the disease was to have a bearing on the response of UK scientists and clinicians for some time. A report of the UKHCDO Hepatitis Working Party dated 1 March 1983 set out what was known of the origins of AIDS and the signs and symptoms of infection.<sup>98</sup> The report noted that the CDC had asked UK Haemophilia Centre Directors to report cases possibly associated with US commercial concentrates and that cases should also be reported to the CDSC. UK haemophilia clinicians were brought into the wider survey of the disease at this time.

**9.73** The report would not, however, have communicated the full extent of the implications for individuals with AIDS. It commented:

<sup>95</sup> *Observer* article, January 1983 [DHF.001.7108]

<sup>96</sup> See Preliminary Report, paragraphs 8.18 and 8.19 for further details.

<sup>97</sup> Notes of Meeting With Immuno at Heathrow Airport, 24 January – Hepatitis Reduced Factor VIII and Factor IX Concentrates for Haemophilia Therapy [SNB.001.4033] at 4035–6

<sup>98</sup> UKHCDO Hepatitis Working Party – The Acquired Immune Deficiency Syndrome (AIDS) [DHF.001.7178]

It is ... possible that the initial phase of the disease ... may not always progress to the final syndrome where marked depletion of the lymphoid cells is the most obvious appearance on histology of lymph nodes. It is therefore evident that the disease is not universally fatal and some patients may recover.<sup>99</sup>

**9.74** The natural history of AIDS was not then understood. Dr Winter commented that while, on the basis of the information then available, it was reasonable to suggest that not every patient infected with HIV would progress to AIDS, there was no basis for the statement that some might recover from AIDS: that was not the case, as events subsequently transpired.<sup>100</sup> The report understated the risk to patients and this was to be a continuing feature of comment for a time.

**9.75** Dr Peter Foster of the Edinburgh Protein Fractionation Centre (PFC – the manufacturer of NHS blood products in Scotland) gave a talk to Professor Ludlam's department on 8 March 1983 on methods for preparing non-infective blood products.<sup>101</sup> The talk was concerned primarily with avoiding or minimising the risk of transmission of hepatitis viruses although, among other problems of interest to blood product manufacturers, he referred to other infectious agents, including AIDS.<sup>102</sup>

**9.76** The Haemophilia and Blood Transfusion Working Group met on 22 March 1983.<sup>103</sup> There was concern that AIDS might appear in the UK and the Haemophilia Society was reported to be attempting to 'reassure its members and put fears of infection from blood products into perspective'. It was hoped that homosexuals and others at risk might be discouraged from being blood donors, although Transfusion Directors were reluctant to upset potential donors by asking questions to which they might take exception.<sup>104</sup> When asked whether enough concern had been expressed at this meeting, Professor Ludlam assured the Inquiry that there was concern and also 'bafflement'. He said that it was clear that it was a possibility, or even probability, that AIDS would come into England and Scotland.<sup>105</sup>

**9.77** Professor Forbes also attended this meeting and, although he had little recollection of the discussions, he recognised that there was a wave of tremendous anxiety about HIV infection and its transmission and, he told the Inquiry, depression in the patients who were being exposed to the possibility of infection. He continued:

I think most people thought that it undoubtedly would appear in the course of time, and already we were starting to look rather differently at our patients to see if they had any of the features that might be an early warning of AIDS.<sup>106</sup>

**9.78** On 28 March 1983, the UK National Institute for Biological Standards and Controls (NIBSC) was sufficiently concerned about the US position (where steps were being taken to avoid blood from high-risk groups in the preparation of certain blood products) that it suggested that the problem of AIDS should be considered at a meeting of the Committee on Safety of Medicines (CSM). The author (name redacted) of a letter of that date thought

<sup>99</sup> Ibid [DHF.001.7178] at 7182

<sup>100</sup> Dr Winter – Day 16, pages 34–35

<sup>101</sup> Outline of talk [SNB.007.3503]

<sup>102</sup> Ibid [SNB.007.3503] at 3507

<sup>103</sup> Minutes of the Haemophilia and Blood Transfusion Working Group [SNB.001.5183]

<sup>104</sup> Ibid [SNB.001.5183] at 5184

<sup>106</sup> Professor Forbes – Day 17, pages 103–104

it would be helpful if the Chairman of the Haemophilia Directors' group, Professor Bloom, could attend and advise the meeting. The author also requested the latest information on the surveillance of the condition in the UK.<sup>107</sup>

**9.79** Professor Bloom was frequently consulted at this time on matters relating to haemophilia patients. The CSM's functions were regulatory. The committee was concerned with the safety of medicines in general and this included the safety of blood. Any clinical investigation of the potential epidemic would have been carried out by the CDSC, the British equivalent of the CDC in the USA.<sup>108</sup>

**9.80** A report prepared by the Council of Europe dated 28 April 1983 summarised the AIDS situation in member states and other countries represented on the committee, as then reported.<sup>109</sup> The report was discussed at the meeting of the Committee of Experts on Blood Transfusion and Immunohaematology in Lisbon held between 16 and 19 May.

**9.81** Low numbers of infections were reported. The UK had eight possible cases, all males and almost all homosexuals. None followed the transfusion of blood or blood products. Most of the European countries reported fewer than five cases and, of those cases, the majority were homosexuals. Belgium had 15 cases affecting both male and female heterosexuals from Zaire (now the Democratic Republic of Congo). West Germany had the highest number of cases, 18, two of whom were haemophilia patients. The other European country to report several cases of AIDS in haemophilia patients was Spain, with three cases of haemophilia patients from the Andalusia region (two were brothers). Cases of AIDS in Canada were also included where there were 31 known patients, 16 of whom had died.

**9.82** The three Spanish cases were reported in *The Lancet* on 30 April 1983.<sup>110</sup> One patient had already died and a second was in hospital, seriously ill. The third had PCP, among other indications of advanced disease, but his general condition had improved with treatment. Prognosis for the survivors was not discussed but would not have been indicative of a benign outcome. Dr Spence Galbraith, Director of the CDSC in England and Wales, contacted the health authorities in Spain and discovered that the three patients had all received Factor VIII concentrate from the USA.<sup>111</sup> As noted below at paragraph 9.99, Dr Galbraith was to take a particular interest in following up these reports.

### **Press reports**

**9.83** On 1 May 1983 an article published in *The Observer* summarised the impact on the US population of 'America's newest and deadliest epidemic'.<sup>112</sup> The newspaper's US correspondent reported that more than 1350 patients in the USA had already been diagnosed as suffering from AIDS. No cure had been found and, given the long incubation period (up to three years), it was feared that thousands of people could be unwitting carriers. The most recent suspected victims were babies and adults who did not fall into any of the identified high-risk categories; it was feared that this disease was spreading to other groups within the community.

<sup>107</sup> Letter dated 28 March 1983 [DHF.001.7168]

<sup>108</sup> Dr Winter – Day 16, page 37

<sup>109</sup> Council of Europe Report [DHF.001.4394]

<sup>110</sup> 'AIDS in haemophilia patients in Spain', *The Lancet*, 30 April 1983 [LIT.001.0403]; Preliminary Report, paragraph 8.23

<sup>111</sup> Letter: 'Action on Aids' dated May 1983 [MIS.001.0005]

<sup>112</sup> *The Observer*, 1 May 1983 [DHF.001.4322]

**9.84** The article stated that more European sufferers had been identified, and that in France there were 29 patients, 13 of whom had died. Eleven haemophilia patients in Europe had been affected and this strengthened suspicions that AIDS could be passed on through blood. The US government was reported to be unwilling to stigmatise homosexuals, already a 'harassed minority', by banning them from donating blood. The US National Hemophilia Foundation, however, believed that this had to be the next step. The US government's official view, expressed by a spokesman for the Food and Drug Administration, was that: 'There [was] no clear cut evidence to show that AIDS [could] be transmitted through blood transfusion'.<sup>113</sup>

**9.85** Also on 1 May 1983, Susan Douglas, journalist for the *Mail on Sunday*, 'revealed exclusively' that two cases of AIDS in haemophilia patients had probably occurred in the UK already.<sup>114</sup> An accompanying opinion piece stated that '[t]he victims were not homosexuals but patients who had been treated with plasma imported from America'. The article continued with speculation that Britain would not be self-sufficient in producing 'this special kind of blood' until 1986. The paragraph concluded with the comment: 'Fortunately there is an alternative. It can be bought from Switzerland'.<sup>115</sup>

**9.86** The tone of an article in *The Daily Mail* on 2 May was equally uncompromising.<sup>116</sup> It stated: 'Government health experts have begun investigating the possibility that Britain is importing blood products from America contaminated with the killer homosexual disease AIDS'. The article concluded: 'According to the Department of Health, the advantage of using imported blood products far outweighs the "slight possibility" that AIDS could be transmitted to patients through [Factor VIII]'.<sup>116</sup>

**9.87** *The Daily Express* also published an article on 2 May and described AIDS as 'The new killer-disease'.<sup>117</sup> The focus of this article was fear of the unknown and fear that it could be a more general sexually transmitted disease also affecting heterosexuals. Dr Vernon Coleman (medical author and researcher) was quoted at the end of the article: 'If we could discover exactly what AIDS is – indeed, IF it is – we might be able to do something to counter it'.

**9.88** These publications caused concern generally and particularly amongst at-risk groups, including haemophilia patients.

### The position of the Haemophilia Society

**9.89** With AIDS now reported and discussed in the UK popular press and the media generally, anxiety grew among people at risk. Anxiety was spread not only by the facts but also by the tone of media comment. Prompted by the media coverage to date, and in particular the *Mail on Sunday* article of 1 May 1983 referred to above, the Haemophilia Society distributed to its members on 4 May 1983 a letter containing a statement by Professor Bloom. He commented that the number of AIDS cases in haemophilia patients was small, that he was unaware of any proven case in 'our own haemophilia population' and (incorrectly) that none had been reported from Germany.

<sup>113</sup> Ibid [DHF.001.4322]

<sup>114</sup> *Mail on Sunday*, 1 May 1983 [DHF.001.4320]

<sup>115</sup> Ibid [DHF.001.4323]

<sup>116</sup> *The Daily Mail*, 2 May 1983 [DHF.001.4328]

<sup>117</sup> *The Daily Express*, 2 May 1983 [DHF.001.4328]

**9.90** In an apparent attempt to reassure Society members, Professor Bloom wrote:

The cause of AIDS is quite unknown and it has not been proven to result from transmission of a specific infective agent in blood products .... Thus whilst it would be wrong to be complacent it would equally be counter-productive to alter our treatment programmes radically.<sup>118</sup>

**9.91** Mr David Watters, former General Secretary of the Haemophilia Society, told the Inquiry how the Society had come to send the letter. He explained that what had prompted the Society's letter was the assertion in the *Mail on Sunday* that the UK did not have to rely on the US for Factor VIII as there was an alternative source in Switzerland. He continued:

[T]hat simply was not true and it made it appear as if we had been allowing people to be treated with suspicious product, whereas there was a known safer source. And of course, the media on its high horse knows better than everyone else what is correct and good for society; in this case they got it quite horribly wrong.<sup>119</sup>

**9.92** Mr Watters further explained that the Society's letter was intended to reassure members that there were no known cases of AIDS in the haemophilia population. He felt that the Society had better information than the media and said: 'the *Mail on Sunday* had quite clearly diagnosed two entirely on its own'.<sup>120</sup>

**9.93** At this time, Mr Watters was receiving telephone calls day and night from people who were worried. He was happy with Professor Bloom's message, bearing in mind that '[p]eople with haemophilia were really between a rock and a hard place: do you discontinue treatment and run the risk of a fatal bleed or do you continue to treat and run a potential other infection risk?'<sup>121</sup>

**9.94** Everyone involved in the framing of the letter considered that reassurance was required. Mr Watters advised that members of the board who had access to faxes saw the letter and he was confident that it was also faxed to members of the medical advisory panel. Nobody expressed dissent from what was said in the letter.<sup>122</sup>

**9.95** The reassurance was, however, based on data that were incorrect and that could have been readily checked. The *Mail on Sunday* article specifically stated that the suspected UK case was in Cardiff where Professor Bloom was Director of the Haemophilia Centre. Based on reports from that centre, a bulletin from the CDSC, dated 6 May 1983, reported the case of AIDS in a 20 year old man with haemophilia in Cardiff. The patient had been ill with 'AIDS-related complex' (ARC) for three months.<sup>123</sup> The report stated that this was the first case of AIDS in a UK haemophilia patient known to the CDSC. Dr Winter thought it possible that Professor Bloom was a laboratory-based specialist, not a clinician, and that he did not know of the case.<sup>124</sup> Dr Winter did not think that a clinician would have made comments such as

<sup>124</sup> Day 16, page 41. However, Dr Cacchia, who had assisted Professor Bloom at Cardiff, said that Professor Bloom was a very 'hands-on' and 'person-centred' clinician as well as a leading academic, which tends to undermine Dr Winter's speculation. Day 83, page 8.

those made by Professor Bloom at the time.<sup>125</sup> Professor Ludlam questioned whether the Cardiff case was AIDS, but at the time the CDSC recognised this and another case, from Bristol, as cases of AIDS.<sup>126</sup>

**9.96** There were also, by this stage, early reports of infection in West Germany. The Council of Europe report of 28 April 1983 dealt with AIDS in two German haemophilia patients.<sup>127</sup> The report, perhaps prepared earlier in April, noted that there were no reports of cases following the transfusion of blood or blood products in the UK.<sup>128</sup> By May the situation was changing.<sup>129</sup> It is unclear how widely the deliberations of the Council would have been read. Dr Winter indicated that the deliberations of the Council of Europe were not perceived as relevant to haemophilia clinical practice.<sup>130</sup> He thought that the recommendations in the report had clearly been written by people who were not 'haemophilia people'.<sup>131</sup> Professor Lever had a similar view: the Council of Europe was not influential in his area of work.<sup>132</sup> As appears in the discussion of screening for HCV, however, transfusionists and virologists did take note of the views of the Council and its expert committees.<sup>133</sup> Whatever the degree of authority otherwise accorded to its statements, the report of infections in Germany was fact and further undermined Professor Bloom's letter. Later reports in December 1983 from the WHO conference in Geneva appear to indicate a significant acceleration in identification of infection between then and October, when 42 cases were reported from West Germany to the WHO.<sup>134</sup>

**9.97** In light of the Haemophilia Centre's report of the Cardiff case to the CDSC in time for the publication in the edition for the week ending 6 May 1983, it is difficult to understand the reference to lack of awareness of cases in 'our own haemophilia population'. The newspaper report had identified Cardiff as the location of the haemophilia patient who had been unwell with ARC for three months before the date of the published letter. Preparations must at least have been in hand by 4 May to report the case as a definitive case of AIDS for publication by the CDSC for the week ending 6 May. If publication by the CDSC was essential to the description of a case as 'definitive' or if the word 'proven' was being used because of the absence of identification of the causative pathogen, Professor Bloom's letter may have been literally accurate but then it would also have been disingenuous. If he did not in fact know of the case, questions would arise concerning arrangements for the dissemination of important and relevant information about patients within his centre.

**9.98** In the UK, the systems for reporting instances of AIDS, which were introduced in 1982, were not well developed by this stage. However, absolute accuracy apart, it is of concern that commentators, such as Professor Bloom in these instances, could publish that there were no reports of disease in the UK and two only in Germany respectively, when of necessity they must have been proceeding on information that was quite wrong in fact. In the case of Professor Bloom, he could not have failed to discover the true position if he

had sought information, even assuming that he could have headed the centre without being aware of such a critical matter affecting a patient there. In the result, the letter was misleading. It gave false reassurance to patients who read it.

### Official responses in the United Kingdom

**9.99** Dr Galbraith responded to the reports he had read. He wrote to Dr Ian Field, DHSS, in May 1983.<sup>135</sup> He commented that the Cardiff case had involved US Factor VIII concentrate and that the case fitted the recognised criteria for a diagnosis of AIDS. He referred to the three Spanish cases (see paragraphs 9.81–9.82) and recent reports from the USA, in particular the case of the multiply-transfused child (see paragraph 9.31). In his supporting paper he commented that the mortality rate of AIDS at that point exceeded 60% and was expected to reach 70%. As a public health doctor, he took a serious view of the threat to haemophilia patients in the UK.

**9.100** Media comment brought a further reaction. There was a special meeting of the Haemophilia Reference Centre Directors at St Thomas' Hospital on 13 May 1983.<sup>136</sup> Recent media publicity about AIDS was said to have caused considerable anxiety to haemophilia patients and their medical attendants as well as the DHSS, making it necessary for the Directors to consider what should be done with regard to the surveillance and reporting of suspected cases and the management of patients. It was noted that, up to that date, one haemophilia patient in the UK was suspected of suffering from AIDS and that, in London, there were reported to be 10 cases of confirmed AIDS in homosexual males. The minutes proceeded:

It was felt that there might be many individuals with evidence of impaired cell-mediated immunity but only a very small number of these might progress to a full-blown picture of the condition. It is important that such individuals are not classified as suffering from AIDS. It was accepted that because of our lack of knowledge of the nature of AIDS, decisions about diagnosis and reporting of suspected cases would prove difficult.<sup>137</sup>

**9.101** At this stage, the viral aetiology of AIDS (that is, knowledge that a virus caused the disease) had not been established by generally accepted evidence. In particular, Robert Gallo and his colleagues had yet to disclose the identification of HTLV-III as the transmissible agent, satisfying US specialists who had not been persuaded by the French research previously published by Luc Montagnier and others.<sup>138</sup> Narrowly defined reporting requirements risked suppressing the prevalence of infection with the (as yet unknown) agent of transmission, however.

### Reporting criteria

**9.102** It was decided that, for reporting purposes, CDC criteria would be used and the importance of opportunistic infection was stressed. A definitive diagnosis would be attached if the patient developed intractable disease. It was noted that many Haemophilia Directors had, up to that point, reserved NHS concentrates for children and mildly affected patients

<sup>135</sup> Dr Galbraith's letter: 'Action on Aids' dated May 1983 [MIS.001.0001], retyped as [MIS.001.0005]; Preliminary Report, para 8.24

<sup>136</sup> Minutes of Special Meeting of Haemophilia Reference Centre Directors on 13 May 1983 [DHF.001.4384]. Preliminary Report, paragraph 8.26

<sup>137</sup> *Ibid* [DHF.001.4384] at 4384–5

<sup>138</sup> As discussed later, the Institut Pasteur reported the discovery of LAV, a virus identical to HTLV-III, in May 1983, but that was not generally accepted at this stage. See also Chapter 29, *The Discovery of HIV and the Development of Screening Tests*.

and it was suggested that it would be 'circumspect' to continue with that policy. It was agreed that there was insufficient evidence to warrant the restriction of the use of imported concentrates in other patients in view of the immense benefits of therapy. It was noted that, once the condition was fully developed, it seemed irreversible so that there would be no clinical benefit to be gained from changing from one type of concentrate to another.

**9.103** The requirement for evidence of intractable disease added to the burden of proof of infection (as had happened previously when a requirement for clinically manifest disease was included in the definition of non-A, non-B Hepatitis infection – see Chapter 15, *Knowledge of Viral Hepatitis 2 – 1975-1985*). There was no requirement for notification of cases of impaired cell-mediated immunity. As a result, the data required for a comprehensive understanding of the epidemiology of the disease were incomplete.

**9.104** Meanwhile, media coverage continued. On 18 May 1983 *The Sun* published an article 'U.S. Gay Blood Plague Kills Three in Britain'.<sup>139</sup>

### *Developing knowledge*

**9.105** Apart from haemophilia clinicians, developing knowledge of AIDS was also of relevance to fractionation scientists (those concerned, that is, with the preparation of blood products). Dr Foster of the PFC attended the meeting of the World Federation of Hemophilia and International Society for Thrombosis and Haemostasis in Sweden in June 1983.<sup>140</sup> He also recorded data provided by Dr Evatt about the spread of AIDS in the USA and elsewhere.<sup>141</sup>

**9.106** The Sub-Committee on Biological Products of the CSM discussed AIDS on 13 July 1983.<sup>142</sup> Reported comments on AIDS provide a clear insight into the understanding of this important body about the epidemic in mid-1983. Transmissibility of the postulated transmissible agent was thought to be low. Risk was thought to be small, so small that it did not justify serious consideration of withdrawal of US commercial concentrates (as had been suggested by Dr Galbraith in his letter to Dr Field, DHSS).<sup>143</sup> These outcomes had been anticipated in a 'suggested agenda' for the meeting.<sup>144</sup> For the proposal to be considered unworthy of serious consideration, however, the perceived risk to the UK community must have been considered small indeed. Unfortunately, this was to prove an inaccurate assessment. It was also noted that both haemophilia doctors and their patients, who saw at first hand the benefits of Factor VIII over cryoprecipitate, did not wish US blood products withdrawn. The committee will have taken this into account. There were 2167 patients with haemophilia receiving treatment in the UK at the time.<sup>145</sup> In England and Wales a high proportion received imported concentrates, while in Scotland the proportion was much lower. Only a relatively small percentage of blood products used in Scotland in 1983 came from the USA.<sup>146</sup> Nevertheless, overall there was a high exposure to risk and a high incidence of infection emerged over time.

<sup>145</sup> Preliminary Report, para 8.44

<sup>146</sup> *Ibid* para 8.42

**9.107** On 14 July 1983, in the House of Lords, Baroness Dudley asked how widespread AIDS was and what steps were being taken to prevent it spreading into the community.<sup>147</sup> Lord Glenarthur (then the Parliamentary Under-Secretary of State, DHSS) replied that 14 cases had been reported to the CDSC and two more were being investigated. There were approximately 60 cases within member states of the Council of Europe. When asked why the UK imported blood products from the USA, Lord Glenarthur said: ‘We have to import Factor VIII, which is an agent used in the cure for haemophiliacs. We shall need to continue to do that until we are self-sufficient ourselves’.

**9.108** At this stage, there was doubt at UK government level whether a link between blood transfusion and AIDS had been established. In the course of his answer to Baroness Dudley, Lord Glenarthur stated:

Although there is no conclusive evidence that AIDS is transmitted by blood or blood products, the department [DHSS] is considering the publication of a leaflet indicating the circumstances in which blood donations should be avoided.<sup>148</sup>

**9.109** ‘No conclusive evidence’, appears to have been a recurring form of words used with some frequency at this time. In a letter to the Association of Scientific, Technical and Managerial Staffs (ASTMS), undated but marked as received on 26 August 1983, Lord Glenarthur referred to the need to emphasise that ‘there is no conclusive evidence that AIDS is transmitted through blood products’.<sup>149</sup> The leaflet anticipated in Lord Glenarthur’s reply on 14 July was issued on 1 September 1983 for use throughout the United Kingdom.<sup>150</sup> A Press Release issued to accompany the leaflet stated: ‘there is no conclusive proof that the disease [AIDS] can be transmitted in blood or in blood products’.<sup>151</sup> On 14 November 1983, in answering a Parliamentary Question in the House of Commons by Edwina Currie MP, Kenneth Clarke MP, Minister of State for Health and Social Services, said: ‘There is no conclusive evidence that acquired immune deficiency syndrome (AIDS) is transmitted by blood products’.<sup>152</sup>

**9.110** In contrast, the leaflet issued on 1 September 1983 for distribution to blood donors included in the series of questions and answers the following: ‘Can AIDS be transmitted by transfusion of blood and blood products?’ with an answer which began: ‘Almost certainly yes ...’, explaining that the risk of transmission was higher to people with haemophilia than to recipients of ordinary blood transfusions.<sup>153</sup>

**9.111** The Haemophilia Society was concerned that there should be no attempt to suspend the importation of US commercial products in the absence of ‘definite evidence’ that that would be necessary. On 15 August 1983, the Coordinator of the Society wrote to a government official regarding a meeting arranged between representatives of the Society and Lord Glenarthur to take place on 8 September 1983.<sup>154</sup> Avoiding the banning

<sup>152</sup> Hansard extract [DHF.001.5064]

<sup>153</sup> Leaflet – ‘AIDS and how it concerns blood donors’ [SGH.002.6675] at 6676

<sup>154</sup> Letter from the coordinator of the Haemophilia Society [DHF.001.4691]. The identity of the recipient of the letter has been removed by redaction.

of importation of concentrates from the USA was one of the issues the Society wanted to discuss. An undated file copy of a letter from Lord Glenarthur to the society records points made at the meeting.<sup>155</sup> He commented that, in considering whether the importation of blood products from the USA should cease, it was deemed necessary to weigh the possible risks of infection with AIDS against the obvious risks arising from inadequate supplies of Factor VIII. He noted that the FDA in the USA had introduced regulations designed to exclude plasma donors presenting a high risk of AIDS but that there was still a considerable quantity of pre-March 1983 stock, both in the UK and in the USA awaiting export. The FDA had decided not to ban the use of this stock, since doing so would cause a crisis in supply, in both the UK and the USA.<sup>156</sup> Importation would, on this view, continue.

**9.112** By letter dated 13 December 1983, Lord Glenarthur wrote to John Maples MP, who had enquired about the government's assessment of risk in light of recent press reports. The letter stated that the cause of AIDS was as yet unknown and that there was no conclusive proof that the disease had been transmitted by US blood products.<sup>157</sup> It proceeded to repeat the information given to the Haemophilia Society that importation would continue, including stock collected before the regulations introduced by the FDA from March 1983.

**9.113** On 5 January 1984, another letter was sent by Lord Glenarthur to the ASTMS. The first full paragraph of the letter appears to indicate that the official view had become qualified (emphasis as in original):

It remains the case that there is no conclusive evidence of the transmission of AIDS through blood products, although the circumstantial evidence is strong.<sup>158</sup>

**9.114** The Department of Health papers also include a photocopy of an article from *The Sunday Times* of 25 March 1984 which records:

Doctors now have conclusive proof that the mysterious and generally fatal ailment known as AIDS has been passed to a hospital patient through a blood transfusion.<sup>159</sup>

**9.115** On what appears to be the reverse of this photocopy, someone has written:

We dropped "there is no conclusive proof that AIDS is transmitted through blood or blood products" from our standard line some time ago.<sup>160</sup>

**9.116** The evidence available suggests that the line was dropped between January and March 1984.

**9.117** It appears that, until the spring of 1984, a highly nuanced use of language had been adopted in communicating the government's position and the Inquiry sought to explore the situation. Within the papers released by the Department of Health, there was

<sup>155</sup> Lord Glenarthur's letter [DHF.001.4573]

<sup>156</sup> At the meeting of the Biological Sub Committee of the CSM on 13 July, it had been commented that concentrates from the USA to be used in the UK should be derived from plasma complying with those regulations, provided supply could be assured. See [DHF.002.8865] at 8866

<sup>157</sup> The Archer Inquiry Report, pages 51–52

<sup>158</sup> Lord Glenarthur's letter, 05 Jan 1984 [SGH.007.6160]

<sup>159</sup> 'New Aids alarm over blood link' – *The Sunday Times*, 25 March 1984 [DHF.001.5335]

<sup>160</sup> Hand-written note [DHF.001.5334]

a photocopy of an excerpt from *The Guardian* published on 19 November 1983 referring to the Bristol haemophilia patient who had died of AIDS (see paragraph 9.125 below). Along the foot of the photocopy, in a handwritten note which appears to have been dated 23 November, the following is written:

Have you seen [this]? On X [a section marked in the article about the Bristol patient] is it OK for me to continue to say "there is no conclusive proof that the disease has been transmitted by American blood products". PS Congratulations on your promotion.<sup>161</sup>

**9.118** In different handwriting, along the top, there is what appears to be a response:

Thanks. Yes it is OK.<sup>162</sup>

**9.119** In 2010, the Inquiry was advised by the Department of Health that the first note was written by a middle-ranking official and that the response was by Dr Diana Walford.<sup>163</sup>

**9.120** The Inquiry asked Dr Walford about the formulation and maintenance of the standard line. With particular reference to the question in November 1983 concerning whether it was OK to say that there was no conclusive evidence of a link between AIDS and blood products, Dr Walford replied that 'given the state of knowledge about AIDS and its causative agent at that time, this was the appropriate answer to the question as posed'.<sup>164</sup>

**9.121** Before testifying at this Inquiry, Dr Winter had provided evidence to the Archer Inquiry. He had said in his submission:

In November 1983, the Health Minister, Kenneth Clark [sic], announced in Parliament that "there was no evidence that AIDS is transmitted by blood products".<sup>165</sup>

**9.122** It was suggested to Dr Winter that his recollection of what Mr Clarke had said was incorrect. In relation to the words 'no conclusive evidence', Dr Winter commented:

What, if you like, I objected to is the clear sentiment. The sentiment is saying, "We have no good evidence that AIDS is due to blood products". I mean, all haemophilia clinicians by this stage clearly believed that commercial blood products could and were transmitting AIDS. So it would have been more appropriate if the Secretary of State had said something to that effect, rather than using that form of words, with its implication that there remained doubt. Technically he was correct but I don't think he realised how fortunate he was, in terms of that, really.<sup>166</sup>

**9.123** The Inquiry is sympathetic to Dr Winter's observations. It is not at all clear what evidence one requires beyond that required for 'near certainty' (the view of the association set out in the leaflet of 1 September 1983) to amount to 'conclusive proof' or 'conclusive

<sup>161</sup> *The Guardian*, 'US Blood Caused AIDS', *The Guardian*, 01 November 1983 [DHF.001.5006]

<sup>162</sup> Hand-written note [DHF.001.5006]

<sup>163</sup> Letter from DoH to the Inquiry, 14 October 2010 [PEN.015.0484]. At that time, Dr Walford was a senior medical civil servant and the medical member of the secretariat to the Advisory Committee on the National Blood Transfusion Service for England and Wales.

<sup>164</sup> Letter from Dr Walford [PEN.010.0079]

<sup>165</sup> Dr Winter's submission to the Archer Inquiry [PEN.015.0283]

<sup>166</sup> Day 16, page 88

evidence' of an association between blood and blood products and transmission of an infective agent in the public health area. The risk of misinterpretation, as evidenced by Dr Winter's comments, appears to have been real, though the Inquiry cannot know whether the use of the standard line did in fact mislead any individual or body. As matters stood, it was not until mid-1984 that there was general (though not even then universal) acceptance that AIDS was caused by parenteral transmission of HIV, as discussed in Chapter 11, *AIDS Aetiology*. As Dr Winter noted, the official position was 'technically' correct, but it risked contributing to a false sense of security. However, at this stage the incidence of AIDS in the UK remained low.

**9.124** Of the 14 cases of AIDS reported to the UK CDSC by 31 July 1983, six were cases of KS without PCP, five were cases of PCP without KS and three involved other opportunistic infections.<sup>167</sup> Five patients, all adult homosexual men, had died. One of the 14 patients, the youngest at 20, was a haemophilia patient.<sup>168</sup>

**9.125** On 10 September 1983, Dr Craske issued an update on the UKHCDO investigation of AIDS cases in patients with blood coagulation disorders.<sup>169</sup> 'The Cardiff patient – reported as a possible case of AIDS in the CDSC Bulletin for the week ending 6 May 1983 – remained in reasonable health.<sup>170</sup> 'The Bristol patient', a mildly affected haemophilia patient aged 57 and considered to be a mild or prodromal case of AIDS (signalling the onset of disease), had remained unwell through June and July and died in August. A post-mortem had revealed PCP. This was considered to be the first confirmed case of death from AIDS possibly associated with transfusion of blood products in the UK. The case clearly met the criteria decided on 13 May: the patient had developed intractable disease. The same cases were reported to the UK Haemophilia Centre Directors' Hepatitis Working Party on 14 September 1983.<sup>171</sup>

### *Haemophilia Reference Centre Directors' meeting*

**9.126** A meeting of the Haemophilia Reference Centre Directors was held on 19 September 1983.<sup>172</sup> Scotland was represented at this meeting by Professor Ludlam. The minutes of the meeting recorded that Dr Craske's paper updating the situation regarding AIDS in the UK was discussed at length.<sup>173</sup> Professor Bloom said that Dr Galbraith of the CDSC was somewhat concerned that he had not heard about the Bristol patient who had died of AIDS. Differing views were expressed about whether it was the responsibility of the centre directors themselves to report directly to the CDSC as well as to Dr Craske. It was agreed that reporting to the CDSC should be through Dr Craske after discussion with the doctor involved in the patient's management. It was also agreed that patients who had received the same batches of NHS or commercial Factor VIII as the Bristol patient should be followed-up. Dr Craske stressed the need for a properly conducted epidemiological study of AIDS in the haemophilia population. It was noted that Dr Peter Jones (Newcastle Haemophilia Centre) and Dr Forbes were both taking part in a forthcoming international study.

<sup>167</sup> 'Surveillance of the acquired immune deficiency syndrome in the United Kingdom, January 1982–July 1983, *British Medical Journal*, 1983; 287:407–408 [LIT.001.0232] at 0233; Preliminary Report, para 8.44

<sup>168</sup> This appears to be the same patient as was reported in the Bulletin of 6 May 1983.

<sup>170</sup> CDSC report for week ending 6th May 1983 [PEN.015.0244]

<sup>171</sup> Minutes of the 12th Meeting of the UK Haemophilia Centre Directors' Hepatitis Working Party held at the Oxford Haemophilia Centre on 14 September 1983 [LOT.003.5434]

<sup>172</sup> Minutes of the Haemophilia Reference Centre Directors meeting [LOT.003.2862]

<sup>173</sup> *Ibid* [LOT.003.2862] at 2864

**9.127** Professor Bloom's update of the May AIDS circular prepared for the Haemophilia Society was approved by the Haemophilia Reference Centre Directors. It was released as a fact sheet, called 'Haemofact A.I.D.S. Release No 2', on 22 September 1983.<sup>174</sup> It reported that there had been one death recorded in a person with haemophilia (the Bristol patient) and that there remained one other suspected case in Cardiff. There had been no other cases relevant to haemophilia patients reported to the PHLS. In the summary, the leaflet stated that the Society had maintained close liaison with all relevant personnel and government departments to ensure the Society's views were known.

**9.128** A representative of the DHSS (probably Dr Diana Walford, the only representative of the Department in attendance) drafted a note of the Haemophilia Reference Centre Directors' meeting. She wrote that the relatives of the man who died in Bristol had taken legal advice and were keen to sue the manufacturers (Alpha and Immuno) of the commercial concentrate which he received in 1981. The author commented: 'If they go ahead, this could put the cat among the pigeons'.<sup>175</sup>

**9.129** The two confirmed cases were reported on 27 September 1983 to the UK Working Party on Transfusion Associated Hepatitis. The current position on AIDS was reviewed by Dr Craske.<sup>176</sup> He reported 20 AIDS cases in the UK, including the two haemophilia patients. In discussion, Dr Howard Thomas of the Royal Free Hospital, London, questioned the diagnoses, especially in the case of the Bristol patient. There was renewed concern among the Directors about responsibility for reporting suspected cases of AIDS. The report of the UKHCDO Hepatitis Working Party (under the chairmanship of Dr Craske) for 1982–83 was published on 28 September 1983.<sup>177</sup> It stated that, up to that time, 16 cases of the syndrome which fitted the criteria used by the CDC and were associated with the transfusion of Factor VIII concentrate had been reported in the USA. Five cases had been reported from Europe. This included a suspect case notified recently in the UK, notified shortly before publication. The report did not disclose the total number of UK cases within the European total. Having regard to the information provided on 27 September, the report was already out of date.

**9.130** The varying descriptions of the patients and their signs and symptoms cause some uncertainty as to the precise numbers of haemophilia patients affected by AIDS at this stage. It appears highly likely, however, that there had been two only who had reached the stage of developing intractable disease, as stipulated by the CDC criteria, and that one of the patients had died in August 1983.

### *Medical Research Council Working Party on AIDS*

**9.131** On 10 October 1983, the Medical Research Council (MRC) Working Party on AIDS met.<sup>178</sup> The position on AIDS was reviewed. The manifestations of AIDS were noted to vary according to both host and environmental factors. The underlying difficulties in assessing the extent of the disease at this time are reflected in some of the discussion reported:

The pattern emerging in early UK cases seemed different in some respects from the American experience .... The laboratory markers for disease were

<sup>178</sup> Minute of Medical Research Council meeting [SNF.001.3759]

well established for AIDS itself but their relevance in screening and in a possible precursor state was not established. The problems of definition and interpretation of these so called precursor syndromes were outlined by several members.<sup>179</sup>

**9.132** The special features arising in relation to haemophilia were discussed. There were said to be varying and considerable periods of incubation (one to four years). It was noted that:

The possibility that AIDS as currently defined was the tip of an iceberg in terms of the range of clinical or subclinical responses to infection with a putative AIDS agent was mentioned; it was recognised that the existence of milder forms would be hard to establish without a marker for such an agent.<sup>180</sup>

**9.133** In reviewing available information on epidemiology, it was noted that in the USA the pattern of the number of cases doubling every six months appeared to be continuing. The UK figure (now standing at 24 cases) indicated that there had been a recent increase almost conforming to a six-month doubling time. It appears from the report of the discussion that, at least among the members of this group, there was an apprehension that the current definition of AIDS for reporting purposes was failing to produce data reflecting the full extent of the problem.<sup>181</sup>

#### *Further meetings*

**9.134** On 17 October 1983, at a meeting of the Advisory Committee of the National Blood Transfusion Service, Dr Walford, DHSS, said that there had been 24 cases of AIDS reported in the UK, two of whom were haemophilia patients and one of whom had died, and that comparison with 'reported incidence in the UK [*sic* – US<sup>182</sup>] haemophilia population' suggested that the UK could anticipate between two to four deaths from the disease among people with haemophilia from the disease.<sup>183</sup> Unfortunately this was to prove to be a considerable underestimate but it may have reflected her understanding of experience in the USA to that date. There was by that stage, in the official view as represented by Dr Walford, 'no conclusive proof of a link between AIDS and blood products' that might have instructed a different assessment of the risk.

**9.135** At the 14th meeting of the UK Haemophilia Centre Directors on the same day, 17 October 1983, Dr Craske presented his paper on AIDS.<sup>184</sup> He outlined his proposals for investigating the UK cases of AIDS in haemophilia patients and proposed follow-up for three years of patients who had received 'suspect batches of concentrate.'

<sup>179</sup> Ibid [SNF.001.3759] at 3760

<sup>180</sup> Ibid [SNF.001.3759] at 3760

<sup>181</sup> Ibid [SNF.001.3759] at 3761

<sup>182</sup> Dr Walford's comment would make better sense if the comparison had been with the reported incidence of AIDS in the 'US' haemophilia population. WHO intelligence at the end of 1983 reported 19 US cases of AIDS in haemophilia patients with no other known risk factor [SNF.001.2575] at 2577, a rate of about 0.09% of the US haemophilia population, with a high mortality. This data would have indicated a very low number for AIDS deaths in the UK haemophilia population of 2167 at 1983 of fewer than two.

<sup>183</sup> Minutes of the Eighth Meeting of the Advisory Committee on the National Blood Transfusion Service Held on 17 October 1983 [SGH.001.8446] at 8449. Dr Walford had attended the meeting of the MRC Working Party on AIDS as a Departmental Observer [SNF.001.3759]

<sup>184</sup> Minutes of the 14<sup>th</sup> UK Haemophilia Centre Directors meeting [SNB.001.7517]

**9.136** Dr Robert Perry of the PFC prepared a note of the meeting in which he listed the numbers and categories of people with AIDS in the USA.<sup>185</sup> He then wrote in relation to the USA:

Crude interpretation of these figures provides the following risk statistics.

Transfusion – 1 in 500,000 at risk

Haemophiliacs – 1.2 in 1000 at risk

Conclusion – Serious disease in haemophiliacs a low possibility??<sup>186</sup>

**9.137** For haemophilia patients the risk factor reflected the information that there had been 15 cases with AIDS in the USA reported at that time. Dr Perry noted the UK situation, as reported, to be that there were 22 patients who met the NIH criteria, 10 of whom had died, and two who were haemophilia patients. Again, comparison with US experience, as understood at the time, would have suggested that very few UK haemophilia patients were at risk of death from AIDS.

**9.138** *The Guardian* of 19 November 1983 reported that the Bristol patient who had died of AIDS in August almost certainly caught the disease from contaminated supplies of imported Factor VIII,<sup>187</sup> quoting from a letter by Bristol clinicians published in *The Lancet* of that date.<sup>188</sup> The haemophilia patient, otherwise fit, had undergone surgery in December 1981 and had received intensive treatment with Factor VIII of US origin. Over 12 days he received 48,253 international units of freeze-dried Factor VIII, his first exposure to commercial concentrate having previously received NHS cryoprecipitate and concentrate manufactured at the Blood Products Laboratory (BPL – the manufacturer of NHS blood products in England and Wales), Elstree, over 10 years at an average rate of 5000 units per annum. His deteriorating condition was traced from the emergence of signs and symptoms early in 1982 until his death. The letter stated:

The diagnosis of AIDS is essentially clinical but our patient met the Centers for Disease Control's criteria in that, without any known cause for immunodeficiency, he had *P. carinii* pneumonia.

**9.139** The patient had become unwell a few weeks after receiving the treatment. The writers thought it highly probable that the development of AIDS was related to his treatment.

**9.140** Dr McClelland and Mr John Watt (Director of the PFC) represented the SNBTS at a WHO conference held in Geneva between 22 and 25 November 1983.<sup>189</sup> The draft report of the conference was circulated on 14 December 1983<sup>190</sup> and contained European data up to October 1983.<sup>191</sup> By 20 October, 268 cases of AIDS had been reported to the European Regional Office of the WHO.<sup>192</sup> These included 24 from the UK (17 diagnosed in 1983) and 42 from the Federal Republic of Germany, as already noted (but none from the GDR, the Soviet part of the country). Reported from France were 94 cases (47 in 1983)

<sup>185</sup> Note of the 14<sup>th</sup> UK Haemophilia Centre Directors meeting [SNB.001.7531]. From surrounding documents, it appears that this was prepared by Dr Perry.

<sup>192</sup> Ibid [SNF.001.2575] at 2609, Table 3

and, from Belgium, 38 cases (24 in 1983). For Europe, four per cent of cases were said to be in people with haemophilia.<sup>193</sup> Coagulation factor concentrates had been implicated. Dr McClelland prepared an initial report on the meeting dated 5 December 1983 for the Scottish Regional Transfusion Directors.<sup>194</sup> The directors met on 8 December and discussed AIDS.<sup>195</sup> Dr McClelland reported that the WHO had received a report of two cases of AIDS in haemophilia patients in the UK. The number of reported cases remained low at this stage.

**9.141** It is apparent that, apart from the general concerns noted by the MRC Working Party on AIDS on 10 October 1983, there was still little anxiety about the position in Scotland at this point. However, media comment was soon to follow. An article by Dr Galbraith in *The Lancet* of 10 December 1983 noted two new UK cases, bringing the total to 26, which included the two haemophilia patients previously recorded.<sup>196</sup> This was taken up in *The Guardian* of 9 December 1983, in which Andrew Veitch, medical correspondent, commented on the emerging pattern, and also noted that the DHSS had reported two new deaths, bringing the total to 12.<sup>197</sup> The comment was balanced and well informed but, in the wider political context, it provided a focus for increasing concern, though the numbers of British haemophilia patients reported as having symptoms remained small at the time. He reported the additional cases and, in the case of haemophilia patients, wrote:

The victims include two haemophiliacs, one of whom died, who are thought to have contracted the disease from contaminated supplies of Factor VIII, the blood clotting agent, imported from the US.

The risk of haemophiliacs developing the disease are put into perspective today by Dr Peter Jones, director of the Newcastle upon Tyne haemophilia centre.

He calculates, in a leading article in the *British Medical Journal*,<sup>198</sup> that the incidence of Aids among haemophiliacs here and in US is about 0.8 per thousands.

....

Fears among British specialists that Aids arrived from the US two years ago and may reach epidemic proportions next year, are born [*sic*] out today by a report from doctors at West Germany's federal Aids working group headquarters in Berlin.

So far 44 cases have been registered and 14 have died, they write in the *Lancet*. Clusters of cases have been identified in Munich, Frankfurt and Berlin.

They warn: 'These data indicate ... that the epidemic is now spreading within the German homosexual community and may increase exponentially. The incubation period of Aids infection suggests that the increase will parallel that observed in 1981-82 in the US, but with a time lag of 1 ½ - 2 years.'

<sup>193</sup> Ibid [SNF.001.2575] at 2578

<sup>194</sup> Initial Report for Scottish Regional Transfusion Directors Meeting on 8 December 1983 [SNF.001.0552]

<sup>196</sup> McEvoy and Galbraith, 'Haemophilia and AIDS in the UK', *The Lancet*, 10 December 1983 [LIT.001.0580]

<sup>197</sup> *The Guardian*, 9.12.1983 [SGF.001.0944] Clearly Mr Veitch had advance sight of *The Lancet* letter as the letter to which he referred was, in fact, published the following day, 10 December.

<sup>198</sup> Jones, 'Acquired immunodeficiency syndrome, hepatitis, and haemophilia', *British Medical Journal*, 10 December 1983 [LIT.001.0243]. Again, Mr Veitch appears to have had advance sight of this publication in writing his report.

**9.142** Dr Jones' calculation was no doubt intended to indicate that the incidence of AIDS among haemophilia patients was low (though broadly consistent with other contemporaneous data) but equating the UK risk with the risk in the USA was unlikely to be comforting to those who had believed that the disease was a phenomenon particularly associated with the USA. Nevertheless, although the trends were beginning to be well established in the USA, it remained the position that, at the end of 1983 and into 1984, AIDS was still not seen by clinicians and officials in this country as presenting a major threat to haemophilia patients in the UK.

**9.143** A meeting arranged by the NIBSC to examine the infectious hazards of blood and blood products, with particular reference to hepatitis and AIDS, was held on 9 February 1984.<sup>199</sup> The SNBTS was represented by Professor John Cash and Dr McClelland. Dr Thomas reported that the most recent information indicated that two UK patients and nine other European patients with haemophilia had contracted AIDS. A recent report from the CDC had also identified 31 people in the USA who had been recipients of a blood transfusion and who had subsequently contracted AIDS.<sup>200</sup> Dr Craske reported on the two UK haemophilia patients who had contracted AIDS, one of whom had died.<sup>201</sup> Concentrates had been received by 231 other patients from one or more of the nine batches used in the case of the two infected patients. These other patients were traced but none had developed AIDS by that point.<sup>202</sup>

**9.144** A report by doctors at the Glasgow Western Infirmary of what appears to have been the first reported case of AIDS in Scotland was published on 11 February 1984.<sup>203</sup> The report, accepted for publication on 3 October 1983, concerned a man who had returned to the UK after working in east Africa for many years and who fulfilled the criteria for AIDS. The signs and symptoms of disease found were said to suggest a disorder of cell-mediated immunity but gave no insight into its cause. The discussion focused on the efficiency of serological testing.

### *European survey*

**9.145** On 30 June 1984 *The Lancet* published an article by Professor Bloom of Cardiff giving the results of his survey of European haemophilia centres.<sup>204</sup> Together with previous data, the survey pointed to 11 cases of AIDS in 13,147 treated haemophilia patients (0.08%). Commenting on his survey of AIDS in Europe at the end of 1983 and early 1984, Professor Bloom wrote:

A relation of AIDS and the other reported disorders to transfusion of imported blood products was not established .... [T]he role of American concentrates in the causation of AIDS in European haemophiliacs must be regarded as unproven .... In view of the immense benefits that haemophiliacs have derived from treatment physicians are naturally reluctant to abandon these agents, with

<sup>203</sup> Shiach et al, 'Pyrexia of undetermined origin, diarrhoea, and primary cerebral lymphoma associated with acquired immunodeficiency', *British Medical Journal*, 1984; 288:449-450 [LIT.001.0219]; Preliminary Report, para 8.76

<sup>204</sup> Bloom, '[AIDS] and other possible immunological disorders in European haemophiliacs', *The Lancet*, 1984; 1452-55 [LIT.001.0409]; Preliminary Report, para 8.87

their hypothetical dangers, in the absence of alternative concentrates which have been proven safer. This attitude may change as information accrues, and haemophilia treatment needs to be monitored world-wide.<sup>205</sup>

**9.146** He stated that no haemophilia patient with AIDS definitely related to transfusion of blood products was reported from West Germany where very large amounts of US Factor VIII concentrates had been used for many years.<sup>206</sup>

**9.147** Reports of cases outside the USA continued to be published. An example, which later came to have relevance in Scotland as part of a comparative study, was a letter in *The Lancet* of 7 July 1984 by Dr Mads Melbye and others dealing with a group of Danish haemophilia patients who had been treated with US Factor VIII concentrate.<sup>207</sup> Of the 22, among the first outside the USA to be tested, 14 were anti-HTLV-III positive.<sup>208</sup>

**9.148** Until this point, reporting in the UK continued to be limited to cases of overt AIDS and AIDS-related diseases. That was to change in the second half of the year for reasons (discussed in Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*) relating to the discovery of LAV/HTLV-III and the consequent ability, shown by Melbye above, to test for the presence of antibodies to the virus, although those discoveries did not have an impact on reporting until the autumn of 1984. As discussed in Chapter 11, *AIDS Aetiology*, the cause of AIDS remained controversial into 1984. With important exceptions, there was little attention paid to the first of the discoveries, the isolation of a Lymphadenopathy Associated Virus (LAV) published in May 1983 by Montagnier and Barré-Sinoussi of the Institut Pasteur in France.

## Summary

**9.149** By July 1984 the following was known:

- AIDS first affected individuals in the USA in 1978 and in the UK in 1979.
- The first recorded cases of seroconversion in Scotland occurred in 1982.
- The first reports of AIDS in the USA were published in June 1981, indicating that the disease might be associated with a significant prodromal period before overt signs and symptoms became apparent.
- Throughout the period covered in this chapter, the disease was considered to be very largely a US problem.
- An early association of AIDS exclusively with sexual behaviour was undermined by emerging reports of cases not associated with such behaviour.
- Knowledge of AIDS among medical practitioners in the UK generally was patchy throughout this period, with few clinicians having direct experience of the disease. Published material was of specialist rather than general interest.

<sup>205</sup> Ibid [LIT.001.0409] at 0412 (See, for example, Professor Bloom's comments.)

<sup>206</sup> Ibid [LIT.001.0409] at 0412

<sup>207</sup> Melbye 'High prevalence of Lymphadenopathy Virus (LAV) in European haemophiliacs', *The Lancet*, 1984; 40–41 [LIT.001.0423]; Preliminary Report, para 8.90

<sup>208</sup> Interestingly, when the research was published in December, it was said that 59% of the Danish patients were infected. 59% of 22 would be 13, not 14.

- Incomplete reporting of instances of AIDS, in the UK and throughout Europe, but especially in Germany, supported a misapprehension in the UK, prevalent until autumn 1983, that blood products imported from the USA were not likely to be associated with transmission of infection to blood disorder patients.
- The epidemic was well established in the USA by July of 1984 both generally and in relation to blood disorder patients.
- Until mid-1984, diagnosis of AIDS in UK patients receiving blood transfusions or blood, blood component or blood product therapy depended on clinical evidence of intractable disease, particularly opportunistic infection such as PCP.
- It was known that the development of opportunistic infection was preceded by cell-mediated immune deficiency, over a period that might be variable but remained significant. However, immune deficiencies, of whatever order of magnitude, were not thought to be diagnostic of a condition likely to progress to AIDS except in very few cases.
- It remained a common view among most commentators in the UK until July 1984 that the cause of AIDS was unknown and that it had not been established that it resulted from transmission of a specific agent in blood products.
- Some scientists, such as fractionation specialists, thought that AIDS was caused by a transmissible agent that could be found in blood and blood products.
- It was believed among haemophilia clinicians that there would be few cases of AIDS among UK blood disorder and transfusion patients.
- Throughout this period, blood disorder therapy continued to include the use of imported commercial factor concentrates from the USA.

## CHAPTER 10

### KNOWLEDGE OF THE GEOGRAPHICAL SPREAD AND PREVALENCE OF HIV/AIDS 2

#### Introduction

**10.1** Until mid-1984, official reports of AIDS cases in the UK, as set out in the last chapter, were of 26 infected individuals, of all populations at risk, of whom two were haemophilia patients. One of the haemophilia patients had died. The diagnosis of AIDS depended on the identification of intractable AIDS-defining disease, at least moderately predictive of a defect in cell-mediated immunity, occurring in a person with no known cause for diminished resistance to that disease ('the CDC criteria').<sup>1</sup> The diseases included Kaposi's sarcoma (KS) and *Pneumocystis carinii* pneumonia (PCP), but covered a wider range for reporting purposes.<sup>2</sup> Evidence of impaired cell-mediated immunity was not reportable; it was not considered sufficient for classification of a case of AIDS. The lack of a requirement for reporting impaired cell-mediated immunity was due particularly to the belief that only a very small number of those so affected might progress to full-blown AIDS. Perceptions of the risk of progression to an AIDS-defining disease changed slowly over a period of two to three years.

**10.2** Meantime, scientific research increased awareness of the prevalence of HIV infection in the UK and quickly demonstrated that the populations at significant risk of progressing to life-threatening disease were, in numerical terms, considerably greater than had previously been appreciated. The major developments happened in late 1984 and 1985. The science is discussed in Chapter 29, *The Discovery of HIV and Development of Screening Tests*. The present chapter is concerned with developing knowledge of the epidemiology and natural history of HIV/AIDS from mid-1984 but principally in the second half of the 1980s.

#### United Kingdom research towards testing for HTLV-III/LAV

##### *Development of the Weiss/Tedder research assay*

**10.3** In early 1984, Professor Robin Weiss of the Chester Beatty Laboratories<sup>3</sup> and Professor Richard Tedder of the Middlesex Hospital Medical School<sup>4</sup> were engaged in research aimed at developing an assay for the detection of HTLV-III/LAV-1 in human blood.<sup>5</sup> They had available, for research purposes only, HTLV-III isolate provided in February 1984 by Mikulas Popovic and Robert Gallo of the National Cancer Institute, Bethesda, and LAV-1 provided in May by Luc Montagnier of the Institut Pasteur, Paris. Their studies showed that the two viruses, later re-designated HIV, were indistinguishable.<sup>6</sup> For the purposes of this chapter, the relevant part of their research related to the study of the prevalence of antibodies to HTLV-III in UK subjects using the Gallo material. They collected sera from 2000 individuals from a wide range of populations, including AIDS patients with clinically diagnosed KS or PCP; patients with PGL (persistent generalised lymphadenopathy: enlarged lymph nodes, a condition that occurs frequently in the latent period of HIV infection); sexual contacts of

<sup>3</sup> Professor Weiss is currently Emeritus Professor of Viral Oncology at UCL Medical School.

<sup>4</sup> Professor Tedder is currently Professor of Medical Virology at UCL Medical School.

<sup>5</sup> See Chapter 29, *The Discovery of HIV and Developments Screening Tests*

<sup>6</sup> Cheingsong-Popov et al, 'Prevalence of antibody to human t-lymphotropic virus type iii in aids and aids-risk patients in Britain', *The Lancet*, 1 September 1984 [LIT.001.0417] at 0419

AIDS patients; homosexual patients positive for Hepatitis B or syphilis and symptom-free cohorts of homosexual volunteers; heterosexual subjects recruited from genito-urinary medicine clinics; intravenous drug users (IVDUs) screened for Hepatitis B; haemophilia patients undergoing regular replacement therapy with clotting factor concentrates; and 1000 randomly selected blood donors. Sera from haemophilia patients had been collected at the Oxford Haemophilia Centre from 1982 onwards and were provided by Dr Charles Rizza, the Director of the centre. Sera from IVDUs were collected in 1983 and 1984. Sera from the other groups had been collected between June 1983 and July 1984. As will be seen in Chapter 29, *The Discovery of HIV and Development of Screening Tests*, the research programme was an extension of earlier research into other retroviruses which expanded to include LAV/HTLV-III. The chronology is important in understanding the relationship between their work and research by others in the field. What they found and the timing of the publication of their findings are the current issues.

**10.4** The results of their research were published on 1 September 1984 by Dr Rachanee Cheingsong-Popov, Professor Weiss, Professor Tedder and others.<sup>7</sup> They commented that there had previously been reported only limited studies of antibody prevalence in groups at risk for AIDS. All of the reports cited were published in 1984. That limitation was consistent with the previous lack of an effective assay and the focus on intractable disease as the prerequisite of an AIDS diagnosis. Attention began to shift from diagnosis of AIDS on that basis to testing for anti-HTLV-III in the course of the year and this landmark paper made a major contribution to the change. The researchers found a striking prevalence of seropositivity<sup>8</sup> among members of the risk groups, including a high prevalence among haemophilia patients who had received pooled clotting factor products (34%). The results for the risk groups studied fitted a pattern that strongly suggested an agent transmissible by sexual or blood contact. The opinion remained tentative, however, and views of the prognosis for those infected were qualified. The article stated:

Even if HTLV-III is causally related to AIDS and PGL, as is strongly suggested by the evidence, we should not assume that these disorders will develop in all patients infected with this retrovirus. Symptomless seroconversion or seroconversion accompanied by mild symptoms is often seen for many infections, including retroviruses. Although it is too early to draw firm conclusions, it seems possible that overt disease will not develop in at least some, and perhaps the majority, of seropositive subjects. On the other hand, the long latent period and a possible role for co-factors in determining the expression of disease make such a suggestion tentative.<sup>9</sup>

**10.5** They commented that the risks had to be set against the relatively low incidence of disease in the haemophilia risk group (roughly 1:1000 as reported at that time) and, further, that the likelihood was that infection resulted from commercial rather than NHS concentrates. There was said to be a relatively low risk at that time of acquiring HTLV-III or AIDS from blood transfusion in the UK.

### Research in Glasgow

**10.6** At about the same time, a similar view was being formulated in Glasgow. In October 1983, Dr Karin Froebel and colleagues had argued against a disease vector specific to blood products from the USA after studying changes in T-cell ratios indicating cell-mediated immune dysfunction in Scottish haemophilia patients exposed to both Scottish (NHS) and commercial (US) Factor VIII concentrates.<sup>10</sup> On 29 October 1984, however, Dr Froebel wrote to Dr Robert Perry at the Scottish National Blood Transfusion Service (SNBTS), stating that, after checking records, she and her colleagues now thought that seropositivity for HTLV-III was in fact strongly associated with the patients having received commercial concentrate, mostly before 1981.<sup>11</sup> Dr Perry wrote to her on 15 November 1984 offering to cooperate in HTLV-III studies and asking for information.<sup>12</sup> With her reply,<sup>13</sup> Dr Froebel sent an abstract of a proposed paper. The full text of the paper in draft, entitled 'Evidence for Transmission of HTLV-III to European Haemophiliacs via US Imported Factor VIII Concentrate', had been prepared by a group including herself and Dr Gallo and a colleague from the US National Cancer Institute.<sup>14</sup> It was based on a comparative study of evidence of transmission of HTLV-III to haemophilia patients in Denmark and Scotland and presented a picture of confidence in locally-manufactured products, concluding that the data indicated that European haemophilia patients exposed to HTLV-III had been so exposed via infected imported Factor VIII concentrate from the USA.

**10.7** Initial comment on the study had been published in a letter to *The Lancet* on 7 July 1984.<sup>15</sup> The final paper was published in *The Lancet* on 22 December 1984.<sup>16</sup> Dr Gallo was among the accredited authors and the Cheingsong-Popov article was cited. The relevant conclusion was that:

Our findings suggest that HTLV-III was distributed through haemophiliac populations by factor VIII concentrate made from US donor material.<sup>17</sup>

**10.8** By the date of publication, the validity of the comments about the safety of local products had already been undermined, so far as Scotland was concerned, by the discovery of HIV infection in 16 Edinburgh haemophilia patients discussed in detail below. The comments remained at least partially correct in a UK context.

**10.9** This marked the end of a period of underestimation of the risk of HTLV-III transmission in Scotland. Evolving events were soon to dispel finally the belief that the blood supplies of the UK and the domestic blood products of the NHS were free from HTLV-III infection. Meantime, however, the Cheingsong-Popov paper received wide publicity and perpetuated the belief that the risks were associated primarily with imported products. Andrew Veitch, medical correspondent, wrote in *The Guardian* of 31 August 1984:

<sup>10</sup> Froebel et al, 'Immunological abnormalities in haemophilia: are they caused by American factor VIII concentrate?' *British Medical Journal*, 1983;287:1091 [LIT.001.0215]

### Study confirms fears on spread of Aids

Fears that the Aids virus is widespread among homosexuals are confirmed today by the biggest British investigation into the disease so far.

The investigators – teams of doctors from seven centres – also found traces of the virus in a third of haemophiliacs given the blood clotting agent, Factor 8: American Factor 8 is strongly implicated.

But, the doctors stress, it seems possible that some of those infected – perhaps even the majority – may not develop the disease.

The number of Aids victims in Britain has risen from 13 in June 1983 to 51 in June this year. By yesterday the Department of Health had confirmed 61 cases, 32 of whom have died. The majority are London homosexuals.

The doctors tested 2000 people for antibodies to the Aids virus – the tell-tale sign that they had been infected. The results are published in *The Lancet* today.

They found the antibodies in 89 per cent of patients with the Aids-related disease, persistent generalised lymphadenopathy (PGL). It has previously been shown that hundreds of homosexuals are suffering from PGL. The symptoms include swollen glands, night sweats, and general malaise.

Antibodies were also found in 59 per cent of homosexuals with mild symptoms; 42 per cent of homosexuals who were sexual contacts of Aids or PGL sufferers; and in 17 per cent of homosexuals who were supposedly healthy or were being routinely screened for hepatitis.

The doctors say their results confirm that the virus, called HTLV-III and discovered earlier this year, is the cause of Aids and PGL. They found antibodies to it in 30 of their 31 Aids patients; the exception had an [un]usually benign form of the illness.<sup>18</sup>

**10.10** The findings had been placed squarely in the public domain. The natural history of HIV infection was still not fully understood and the relative safety of domestic blood supplies was given emphasis.

### *The Weiss/Tedder research assay and early testing in the United Kingdom*

**10.11** Change was, however, imminent. The Weiss/Tedder research assay for HTLV-III, as reported by Dr Cheingsong-Popov and colleagues, was more widely used in the autumn. Haemophilia clinicians provided archived samples of serum from their haemophilia patients for testing and a high prevalence of HTLV-III infection was observed. For example, Dr Peter Kernoff at the Royal Free Hospital in London submitted stored samples of sera from his haemophilia patients to Professor Tedder in October 1984. More than a hundred samples tested positive. Dr Kernoff then had a further series of tests of samples carried out on stored blood samples to determine when his patients had become infected. Almost all of the patients were infected between 1980 and 1982. As no antibody was found in any sample from before 1979, it appeared that HIV had not entered the blood supply before

---

<sup>18</sup> 'Study confirms fears on spread of AIDS', *The Guardian* 31.8.84 [SGF.001.0930]

that date. If Scotland had been dependent on imported products to the extent England and Wales had been, it is likely that the incidence of HIV infection in Scotland would have been of the same order as that in England and Wales.<sup>19</sup>

**10.12** In submitting stored samples for testing, Dr Kernoff was following the general practice of the day.<sup>20</sup> His actions reflected growing apprehension among haemophilia clinicians that factor concentrate therapy might have caused widespread infection within the haemophilia population. Dr Mark Winter said that at that time a haemophilia clinician who had stored samples would submit them for testing without consulting the patients and that samples were stored in case they might be needed for such a purpose.<sup>21</sup> The patient would, however, have been consulted if a fresh sample was required.<sup>22</sup> It is understood that Dr Kernoff did not consult the patients before submitting the samples to Professor Tedder.<sup>23</sup> Dr Winter did not have stored samples.<sup>24</sup> He had to invite his patients to come specially and to explain why he wanted additional blood. Dr Winter obtained and sent 31 samples from his own haemophilia centre at Kent and Canterbury Hospital to Professor Tedder for testing. On 26 October 1984, he received the results: 30 were positive for HIV.<sup>25</sup>

**10.13** On 23 October 1984 Dr John Craske of the Public Health Laboratory Service (PHLS), Withington Hospital, Manchester, circulated a letter to haemophilia clinicians.<sup>26</sup> He advised that a batch of Factor VIII concentrate from the Blood Products Laboratory (BPL), the manufacturer of NHS concentrates in England, had been found to be infected with HTLV-III. He warned of the possible risk of infection with HTLV-III and subsequent development of AIDS. The letter stated that only a proportion of those transfused with an infected batch were likely to contract HTLV-III infection. It commented:

So far 21 patients are known to me who have clinical features of AIDS or the AIDS related complex. It is likely that the proportion of patients who contract HTLV-3 infection who contract AIDS will be of the order of 1/100 – 1/500.<sup>27</sup>

**10.14** The long-term prognosis for patients with HTLV-III infection was said to be unknown.

**10.15** By the end of October 1984, among haemophilia clinicians in the UK generally, there was growing awareness that HTLV-III infection could be, and had been, contracted from Factor VIII concentrate and that transmission could be associated with domestic as well as imported products. Between the end of October and the end of the year, further intelligence emerged in Scotland.<sup>28</sup>

<sup>19</sup> Dr Winter – Day 16, pages 101–6. As noted in paragraph 9.10 of Chapter 9, *Knowledge of the Geographical Spread and Prevalence Of HIV/AIDS 1*, the most up-to-date data available to the Inquiry indicate that for the UK, excluding Scotland, 1310 patients with bleeding disorders tested positive for HIV by April 2012. Scotland has roughly 10% of the UK haemophilia population but only 60 patients treated in Scotland tested positive. See also Chapter 3, *Statistics*.

<sup>20</sup> For more detailed discussion of the ethical issues surrounding the testing of stored samples, please see Chapters 32 and 33.

### **'The Edinburgh Cohort': the initial disclosure**

**10.16** Any residual complacency in Scotland was shattered by the discovery that a group of Edinburgh patients ('the Edinburgh Cohort') who had received Factor VIII concentrate therapy manufactured at the Protein Fractionation Centre (PFC) in Edinburgh, some exclusively and some almost exclusively, had developed antibodies to HTLV-III during 1984. In the immediate aftermath of the discovery it was thought that the infections must be attributed to products manufactured at the PFC (the Scottish equivalent of the BPL in England).<sup>29</sup> Evidence available to the Inquiry relating to the events surrounding the discovery was at times inconsistent and a little confused. The news clearly had a disturbing effect on those who first heard it and witnesses' recollections reflected the degree of turmoil that affected the SNBTS and haemophilia circles when the information emerged.

**10.17** Dr Brian McClelland, Director of the Edinburgh and East of Scotland Blood Transfusion Service, gave an account of events in his written statement to the Inquiry. Professor Christopher Ludlam, Director of the Edinburgh Haemophilia Centre, telephoned him at home on the evening of Friday 26 October 1984 to inform him that six patients with haemophilia under his (Professor Ludlam's) care had developed antibodies to HTLV-III. The tests had been performed in a research laboratory by Professor Tedder.<sup>30</sup> The date, and the number of patients affected, gave rise to discussion in the course of the oral hearings of the Inquiry.

**10.18** There had been a meeting of the PFC heads of department on the morning of 26 October 1984.<sup>31</sup> The minutes of the meeting indicate that Dr Perry was concerned that the PFC, of which he was Director,<sup>32</sup> might be asked, in the future, what plans had been made to reduce AIDS infection in blood products. He proposed, and it was agreed, that it would be useful to collate all information and data on heat-treated products and that further meetings should be arranged to discuss this matter.<sup>33</sup>

**10.19** The Inquiry explored the possibility that Dr Perry and his colleagues had already been informed of the HTLV-III transmissions in Edinburgh by this stage.<sup>34</sup> On the written and oral evidence available, it is unlikely that they had.<sup>35</sup> The picture that emerged, however, was of a state of some confusion among this group as information (not always consistent or comprehensive) was exchanged and people began to respond to the events as they evolved.

**10.20** Dr Bruce Cuthbertson, SNBTS, said that he remembered that it was definitely Dr McClelland who phoned him and told him that there had been evidence of infection in three Edinburgh haemophilia patients. He also remembered clearly a meeting with Dr McClelland and Dr Perry approximately a week to 10 days later where they went through the analysis that Dr McClelland had done with Professor Ludlam which showed which batches of Factor VIII had been received by the 16 infected patients identified by that time.<sup>36</sup>

<sup>29</sup> Letter from Dr McClelland to Dr Cash dated 15 November 1984 re analysis of PFC Factor VIII batches [SNF.001.3624]

<sup>30</sup> Dr McClelland's Witness Statement [PEN.011.0062] at 0063

<sup>31</sup> Minutes of a Meeting of Heads of Department/Section Managers held on Friday 26 October 1984 [SNB.010.3479]. Dr Perry told the Inquiry that the heads of department meetings were held regularly on Friday mornings at this time: Day 42, pages 52–3.

<sup>32</sup> Dr Perry had been Quality Control Inspector at the PFC from 1981–1984. He was appointed Acting Director in 1984 and the role was made substantive the following year, 1985. See Day 11, pages 93–4.

<sup>36</sup> Day 46, page 76

**10.21** Dr Foster's evidence was that he first learned of the infections in late October 1984, when he overheard a telephone conversation in Dr Cuthbertson's office.<sup>37</sup> The call was, he thought initially, from Dr McClelland, but it might have been from Dr Frank Boulton, Consultant in Haematology and Blood Transfusion at the Royal Infirmary of Edinburgh (RIE). Dr Cuthbertson said that Dr Foster had told him about the call over the years but that he could not himself remember the event. However, he said of Dr Foster:

It's certainly true that he was in an adjacent office and I'm sure when the information came from Dr McClelland, that my voice would have risen by several octaves.<sup>38</sup>

**10.22** Steps were immediately taken to identify the batch of concentrate which was responsible for the infection of Professor Ludlam's patients. Professor Ludlam and Dr McClelland gave evidence about this period. On 29 or 30 October Professor Ludlam established from examination of transfusion records that three of the initial group of patients who had developed antibodies had received material from batch 023110090.<sup>39</sup> On 2 November 1984 Professor Ludlam received further data from Professor Tedder which indicated that in total 15 or 16 patients who had received that batch had tested positive for the HIV antibody. Three other patients were added on further analysis. Fourteen out of 32 patients who had received material from the batch remained uninfected. On 3 November 1984 Dr McClelland and Dr Frank Boulton contacted all Scottish and Northern Ireland Transfusion Centres and arranged for batch 023110090 to be recalled.<sup>40</sup>

**10.23** It was to be mid-November before a written account was prepared within the SNBTS and, by then, a certain amount of clarification of the history of events had evidently occurred. However, the group of HIV-infected haemophilia patients that was to become known as 'the Edinburgh Cohort' had been discovered at the end of October.

**10.24** Dr Perry stressed that it had never been established conclusively that batch 023110090 was infective but, at the time, the SNBTS proceeded on the basis that it was 'a justifiable, though unproven, assumption'<sup>41</sup> that the batch was responsible for the infections. He explained that the decision to recall was an example of an application of 'the precautionary principle'. His understanding of that principle was that, where there was evidence available to a manufacturer that a medical risk associated with a particular product may exist, it was incumbent upon him and the supplier to take action to mitigate that risk.<sup>42</sup>

**10.25** On 15 November 1984, Dr McClelland wrote to Professor John Cash, Medical Director of the SNBTS:

I have had several discussions with Dr Christopher Ludlam following the discovery that some recipients of PFC Factor VIII have developed antibodies to HTLVIII during 1984 ....

<sup>41</sup> 'Actions surrounding FVIII Batch 023110090' [PEN.016.1258] at 1263

<sup>42</sup> Day 38, pages 13–14

As I reported to the Scottish RTDS last week, it appeared that there are, so far, 16 patients in whom seroconversion is known to have occurred during 1984 and who have received exclusively PFC factor VIII, or (in one case only) commercial factor VIII several years ago which can be discounted from the present problem.

Initial analysis by Dr Ludlam and Dr Tedder showed that one batch of product had been received by all but one of the 16 patients and therefore was highly suspect. This batch (023110090) has been withdrawn.<sup>43</sup>

**10.26** The batch assumed to have been implicated had been identified and action had been taken. After examination of the records, it was concluded that no other recent batch stood out as being 'distinctively strongly implicated' and there was therefore thought to be no obvious basis on which to advise a selective withdrawal of any other material.

## Reactions to developing knowledge in late 1984

### *Official reactions*

**10.27** Following on the media comment by Andrew Veitch and others<sup>44</sup> and the discovery of the Edinburgh Cohort, the incidence of disease in the Scottish population moved into the political arena. In a parliamentary answer on 28 November 1984 relating to the incidence of AIDS in Scotland, it was announced that there were three confirmed cases by 26 November.<sup>45</sup>

**10.28** On 29 November 1984, the SNBTS and Haemophilia Centre Directors met specially to discuss the implications of the recent findings of HTLV-III infection in Scottish haemophilia patients, measures being taken by the SNBTS to prevent the spread of AIDS by blood products and the media attention associated with these developments.<sup>46</sup> All relevant agencies in Scotland were clearly informed of the incidence of infection as understood at that time.

**10.29** At that meeting, outbreaks in three centres were discussed. Professor Ludlam discussed the Edinburgh Cohort and Professor Charles Forbes described the findings of the study of patients at the Glasgow Royal Infirmary and Danish patients.<sup>47</sup> Dr Brenda Gibson reported the anxiety felt by parents of children with haemophilia: five out of 10 children treated at the Royal Hospital for Sick Children, Yorkhill, Glasgow, where imported Factor VIII concentrate had been widely used, were HTLV-III antibody positive.

**10.30** At a meeting of the SNBTS Directors on 11 December 1984, Dr McClelland reported that he had attended a meeting of the National Blood Transfusion Service Working Group on AIDS which had taken place on 27 November 1984.<sup>48</sup> He reported that Dr Marcella Contreras had run a trial of a New York Blood Center questionnaire in the West London Donor Centre, offering donors the chance to elect for their blood to be used for research if they belonged to a risk group. A small number had agreed to do so. All of the declared homosexuals followed up were HTLV-III antibody-negative on testing.

**10.31** On 30 November 1984, Dr Craske wrote to Dr Ludlam providing materials for investigation of the cases of infection in Edinburgh patients. He stated that certain ‘facts’ might help Dr Ludlam appreciate the position. In summary, these included:

- (i) Only a proportion of the patients transfused with an infected batch were likely to contract HTLV-III infection.
- (ii) Some patients who had received commercial factor VIII since 1 January 1980 would already have contracted HTLV-III infection from other infected batches.
- (iii) The proportion of patients infected with HTLV-III who would eventually contract AIDS was unknown but, as serum from 34% of symptomless haemophilia patients was positive for HTLV-III antibody (the Cheingsong-Popov finding), it was thought likely that a significant proportion of patients would remain in good health. He narrated that by that date 21 patients had been reported to him as having the clinical features of AIDS (four patients) or the AIDS-related complex (17 patients). He said that it was likely that the proportion of patients with HTLV-III infection who developed AIDS would be of the order of 1/100–1/500.
- (iv) The long term prognosis for patients with HTLV-III infection was said to be unknown. The incubation period of AIDS, based on projection of the epidemic curve at the CDC, was from nine months to six years, with a mean of four years.
- (v) There was evidence that HTLV-III infection could be transmitted by sexual contact. Therefore some sexual partners of recipients of Factor VIII contaminated with HTLV-III might be at risk.
- (vi) Those patients who were likely to transmit infection, or who were likely to contract AIDS, could not yet be distinguished by means of laboratory tests.<sup>49</sup>

**10.32** Some of these statements proved to be wrong.<sup>50</sup> It was not likely that a significant proportion of patients would remain in good health and it was not likely that the proportion of patients who contracted HTLV-III infection and went on to develop AIDS would be of the order of 1/100–1/500. Over a short period at the end of the year results of tests on sera were rapidly changing perceptions. Dr Craske’s letter set out clearly one set of perceptions about the disease at this time and reflected some of the ‘known unknowns’ as then understood.

**10.33** The UK Haemophilia Reference Centre Directors met on 10 December 1984.<sup>51</sup> By this time, some 800 UK haemophilia patients had been tested for the antibody: the prevalence in haemophilia patients overall was about 35%, but 75% in patients with severe haemophilia.<sup>52</sup> Professor Ludlam is reported to have ‘confirmed that in Scotland, some patients who were previously antibody +ve are now -ve.’<sup>53</sup> Haemophilia Directors wanted to test all of their patients.

<sup>49</sup> Summarised from a letter from Dr Craske to Dr Ludlam dated 30 November 1984 re: Suspect Batches of Edinburgh Factor VIII and Factor IX [LOT.003.4331] at 4332

<sup>50</sup> Dr Winter – Day 16, page 116

<sup>51</sup> Meeting of the Haemophilia Reference Centre Directors – 10 December 1984 [DHF.003.0898]; Notes of the Haemophilia Reference Centre Directors Meeting Blood Products Laboratory Elstree, 10 December 1984 [SNF.001.3850]. The Haemophilia Reference Centre Directors was a committee of UKHCDO and Drs Ludlam, Cash and Forbes were in attendance. More detail of events from this point until the end of 1984 are set out in the Preliminary Report at paragraphs 8.116–8.119

<sup>52</sup> Meeting of the Haemophilia Reference Centre Directors – 10 December 1984 [DHF.003.0898]

<sup>53</sup> Notes of the Haemophilia Reference Centre Directors Meeting Blood Products Laboratory Elstree, 10 December 1984 [SNF.001.3850] at 3853. From later discussion of infection in the Edinburgh Cohort, the record appears to be wrong: some patients who had been negative before receiving the implicated batch were subsequently found to be positive. Some were found to be negative before and after receiving the implicated batch.

**10.34** It was thought that there was a clear need for research to determine prevalence in the UK. A report of the meeting noted a view that inconsistencies in the results of the tests revealed that a study of the haemophilia population would provide invaluable material to increase knowledge of the disease. There was a wide-ranging discussion on a number of important issues but few conclusions were drawn by the haemophilia clinicians present. The prevalence of infection was far from clear and, furthermore, the likelihood of developing AIDS for those who were HTLV-III positive was unknown.

**10.35** On 14 December 1984, the United Kingdom Haemophilia Centre Doctors Organisation (UKHCDO) produced an 'AIDS Advisory Document.'<sup>54</sup> The background information provided included data on infection, as understood by the UKHCDO. In the USA, where there had been over 6000 cases of AIDS, 52 haemophilia patients had been infected. It was said that in the UK there had been 102 cases of AIDS with three reported haemophilia patient cases and 'no doubt other cases ... developing.'

### *Press reports*

**10.36** In the media there was more reporting. A *Daily Express* article dated 21 December 1984 stated:

56 are given AIDS killer blood: Alert as homosexual admits being a donor.

Blood which has been infected with the killer AIDS virus has been given to 56 people, it was revealed yesterday.

Fifteen of the recipients are Scots. Another 32, including a pregnant woman, are from England, and nine others are from Wales.

Most are haemophiliacs but none has yet contracted the disease – although it has an incubation period of up to four years.

Shocked experts at the Blood Transfusion Service made the discovery when the patients mysteriously developed antibodies to the AIDS virus, which is normally transmitted by homosexuals.

Then horrified doctors at a Bournemouth hospital discovered that a young homosexual who is seriously ill with AIDS had been a regular blood donor all over England.

His blood was used for transfusions to patients in the Midlands and the North, but mainly in the South and in Wales. The contaminated blood given to Scots patients is not thought to come from the same source. 'We are still trying to identify the donor' said a Scottish Office spokesman ....

The AIDS virus was discovered among the 15 Scots patients when recently developed tests showed up traces of antibody to the disease in their blood.

Dr Frank Boulton, deputy head of the Edinburgh Blood Transfusion Service said: 'Previously, the only way that AIDS was diagnosed was by the illness itself. But the tests have not been around long enough for us to know what degree of immunity the presence of antibodies indicates.'<sup>55</sup>

<sup>54</sup> AIDS advisory document [SGF.001.2388]; Preliminary Report, para 8.117

<sup>55</sup> '56 are given AIDS killer blood', *The Daily Express*, 21.12.84: [SGF.001.0904]

**10.37** In *The Scotsman* of 22 December 1984, William Paul wrote:

AIDS 'barrier' proves illusory

With the benefit of hindsight, it is now possible for doctors to reflect on the inevitability of AIDS ... gaining a foothold in Scotland.

The disease has largely established itself in Europe and in England since originating in the U.S. and Dr Brian McClelland, director of the Edinburgh and South-East Scotland Blood Transfusion Service, admitted yesterday that it would not have been realistic to expect Scotland to be by-passed.

Even so, Scotland's self-sufficiency in blood and blood products was seen as a significant barrier and the medical profession must have experienced a sense of disappointment when routine tests on haemophiliacs at Edinburgh Royal Infirmary recently uncovered the fact that 15, or possibly 16, of them had contracted the HTLV 3 virus which can cause AIDS.

The virus was transmitted in injections of the blood-clotting agent Factor 8, used by most haemophiliacs to control their condition, which had been prepared from a particular batch of plasma, now identified and withdrawn. Its source was a blood donation given somewhere in the East of Scotland about 12 months ago.

Government scientists are now working to trace the donor but it is by no means certain that they will be successful as plasma is made up from many thousands of individual blood donations.

The balance of probability, according to Dr McClelland, is that the donor of the contaminated blood was a practising homosexual male because that is the section of the population considered to be most at risk from the disease ....

Dr McClelland prefers to think that the contaminated blood must have been donated unwittingly, but cannot rule out the possibility that the donor deliberately went ahead knowing himself to be a member of the at-risk groups ....

'If we had to be 100 per cent certain of the purity of all the blood we turn out we would have to cease operations', Dr McClelland said.

'But the risk to people from not having blood available would be far greater than the risk of AIDS being transmitted for the foreseeable future. The chances of getting AIDS virus from a transfusion are put at a million to one.'

The haemophiliacs in Edinburgh who have been told their blood has produced antibodies to fight the AIDS virus are all described as clinically very well. The odds against them actually developing symptoms of the disease proper ... are said to be 2000 to one.<sup>56</sup>

---

<sup>56</sup> 'AIDS "barrier" proves illusory', *The Scotsman*, 22.12.84 [SGH.002.6484]

**10.38** The quoted risk of 2000:1 against developing the disease proper was clearly very wrong indeed and, even at that time, was more optimistic than other estimates. The source of some of the information in these media reports is unclear. However, accuracy apart, the extent and tone of media comment reflected growing public concern about the spread of the epidemic.

**10.39** In and after 1985, there was intense interest in the Edinburgh Cohort. The patients comprised in the group were studied by clinicians and scientists seeking more information about HIV and AIDS. Several of the articles published about this group of people emphasised the value from a research point of view of being able to study the disease in a group assumed to have had a common source of infection.<sup>57</sup> Several of the articles are referred to in the Preliminary Report at paragraphs 8.205–8.214. It will be appropriate to return to some of these in the context of other developments.

### 1984–1985

#### *HIV in the United Kingdom: a matter of public health*

**10.40** With the discovery of the Edinburgh Cohort, the risk of transmission of HIV by SNBTS factor concentrate, despite the exclusive use of Scottish blood donations in its manufacture, was demonstrated and there was no longer room for differentiating Scottish patients from others at risk, so far as exposure to the epidemic by means of blood, blood components or blood products was concerned. Advice and comment took on a more general character thereafter.

**10.41** An editorial in *The Lancet* of 22 December 1984 (the issue in which the article discussed at paragraph 10.7, above, was also published) contained discussion of 'Blood transfusion, haemophilia and AIDS'.<sup>58</sup> It noted that 52 haemophilia-associated cases of AIDS had been reported in the USA and three in the UK. The overall prevalence of AIDS in treated US haemophilia patients was about twice that in Europe but it was thought that in countries that used Factor VIII concentrate from the USA the number was likely to increase. This obvious inference had previously been resisted but it is difficult to understand how a product manufactured by a given pharmaceutical company for general distribution could have a higher rate of infectivity in its country of origin, the USA, than in importing countries abroad. The prevalence of HTLV-III infection in homosexuals and others seemed to be increasing rapidly in countries outside the USA. It was observed that contamination of local blood products could only be a matter of time. The editorial discussed the options for treatment of blood disorders against this background.

**10.42** There was growing concern about public health. A Ministerial answer by Kenneth Clarke, MP, then Minister of State for Health, to a Parliamentary Question on 21 January 1985 reflects the position of the government at the time:

We are considering the public health implications of AIDS and what further steps might be taken to control it. We have established an expert advisory group<sup>59</sup> to advise the health departments in the United Kingdom, whose members will include experts on all aspects of the disease. Their advice will be valuable in assisting the formulation of a strategy for prevention and control.

<sup>57</sup> See, for example, Preliminary Report, para 8.205

<sup>58</sup> 'Blood Transfusion, Haemophilia, and AIDS', *The Lancet*, 1984; 324:1433–35 [LIT.001.0446]. See Preliminary Report para 8.119 for further details.

<sup>59</sup> The members of the expert advisory group are listed at [SNF.001.3323]

There is at present no vaccine against AIDS or specific treatment, but general preventive measures and health education have a major part to play in controlling the disease ....

Internationally, we are in touch with the Centers for Disease Control in the United States and the World Health Organisation AIDS Reference Centre in Paris, which have considerable data on the disease. Research in this country is proceeding through five projects funded by the Government through the Medical Research Council.<sup>60</sup>

**10.43** He answered further questions (i) to the effect that AIDS was not a notifiable disease under the Public Health (Control of Disease) Act 1984; (ii) relating to monitoring arrangements; and (iii) relating to the intention to make the disease notifiable and the practical implications of that:

Interim guidelines drawn up by the Advisory Committee on Dangerous Pathogens<sup>61</sup> on the safe handling of AIDS patients have recently been published jointly by our Department and the Health and Safety Commission. These set out the measures which should be taken to protect clinical and laboratory staff who come into contact with patients suffering from AIDS or with specimens taken from them. We are taking steps to reduce the risk of the spread of AIDS through blood transfusion and the use of blood products. We are strengthening our efforts to dissuade those in AIDS high-risk groups from donating blood, and our revised leaflet 'AIDS Important New Information for Blood Donors' will be distributed individually to all donors. We are also considering the need to screen blood donations for the HTLV III antibody. Supplies of heat-treated factor VIII for haemophiliacs will shortly be made available to the NHS from the Central Blood Laboratories Authority.<sup>62</sup>

### *Reaction in Scotland*

**10.44** In Scotland, steps had already been taken to protect staff at the PFC. On 31 December 1984 Dr Perry had issued a memorandum setting out the current understanding of AIDS risk and encouraging the use of safe working practices.<sup>63</sup> There was an understandable emphasis on staff safety but some of the information provided in the memorandum gives an insight into the impact of media comment and the understanding within the PFC at the time: the memorandum distinguished transfusion from factor concentrate therapy; and it noted that there had been no cases of AIDS in Scotland or Northern Ireland associated with transfusions of blood or blood products from the SNBTS and that some haemophilia patients had HTLV-III antibodies, evidence of exposure to the AIDS virus, but that none had symptoms of AIDS. It narrated that the patients who had been exposed to the AIDS virus all received some vials from the suspect batch and that some had also received material from a number of other batches. It was stated that the fact that these patients had evidence of exposure to HTLV-III did not necessarily mean that they would go on to develop AIDS. Employees were encouraged to work safely but they were reassured that at that time there had been no cases (worldwide) of AIDS in any centres manufacturing blood products despite the fact that the spread of AIDS in the USA was some two to three years ahead of Europe.

<sup>60</sup> Written Parliamentary Answer, 21 January 1985, columns 345–348 [DHF.001.9150]

<sup>61</sup> Acquired Immune Deficiency Syndrome (AIDS) – Interim Guidelines [DHF.001.6071]

<sup>62</sup> Written Parliamentary Answer, 21 January 1985, columns 345–348 [DHF.001.9150]

<sup>63</sup> Memorandum from Dr Perry to All Staff dated 31 December 1984 re AIDS [SNB.004.8843]

**10.45** Dr Perry distributed a second memorandum to all PFC staff, dated 31 January 1985, discussing further the transfusion risks associated with blood components.<sup>64</sup> Red cells and platelets had been used normally by Regional Transfusion Centres (RTCs) and there was no evidence to date to indicate that the recipients of these products had developed HTLV-III antibodies. He provided information on attempts to identify donors who had contributed to the batch implicated in the infection of the Edinburgh Cohort and to quarantine all plasma from those individuals who had been identified and who subsequently gave donations. The memorandum narrated:

The decision to quarantine this plasma was taken to safeguard both product and staff safety in the belief that additional evidence and further investigation of repeat donations would identify the infective donation(s) and permit the remaining donations to be entered into process. As you know, a suitable test is not yet available for large scale application to individual donations with the result that it is not possible at the present time or in the foreseeable future to establish the relative infectivity of plasma pools or product batches. On this basis, the quarantined plasma was released for process. You will also be aware of the fact that plasma from these donors has inevitably entered process on previous occasions. While this does not necessarily provide comfort or reassurance, one must conclude that, at this stage, it is impossible to judge that some plasma is 'safer' than others or that one pool of plasma represents a higher risk than others either from a patient or staff safety point of view.<sup>65</sup>

**10.46** On 4 February 1985, the Scottish Home and Health Department (SHHD) distributed the advice of the Advisory Committee on Dangerous Pathogens in the form of 'Interim Guidelines on AIDS' (dated December 1984).<sup>66</sup> Their interim character was emphasised but the guidelines provide a useful summary of contemporaneous knowledge of the disease and its clinical course.<sup>67</sup> It was noted that HTLV-III and LAV had been recovered from patients with AIDS. It was said that the two agents (in fact, it would later be discovered that they were the same) had also been isolated from patients with PGL, haemophilia patients and apparently healthy male homosexuals. The prevalence of infection in AIDS patients, haemophilia patients who had received pooled clotting factors and others was tabulated. Eighty-eight cases had been reported between *The Lancet* report of 12 December 1981 and October 1984 and 37 individuals had died. One patient had been diagnosed retrospectively as having been infected in 1979. The cases were grouped according to their prime recognisable condition:

Kaposi's sarcoma (KS)	30
Pneumocystis carinii pneumonia (PCP)	32
KS plus PCP	5
Other opportunistic infections	20
Cerebral lymphoma	1 <sup>68</sup>

<sup>64</sup> Memorandum from Dr Perry to All Staff dated 31 January 1985 re AIDS [SNF.001.3715]

<sup>65</sup> Ibid, [SNF.001.3715]. This conclusion led to the release of plasma for processing.

<sup>66</sup> Interim Guidelines [DHF.001.6071]

<sup>67</sup> The interim guidance was accompanied by a letter: an example is [SGH.001.0360]

<sup>68</sup> Interim guidelines [DHF.001.6071] at 6077

**10.47** Of the 88 cases, over 75% were male homosexuals while the remainder were patients with direct or indirect contact with central Africa, recipients of pooled clotting factors and a small group with no recognised risk factor. The Interim Guidelines commented:

If the trend in the UK follows that seen in the USA we can expect an exponential increase in the number of cases of clinical AIDS diagnosed. Furthermore the serological studies ... seem to indicate that whereas the most severe outcome of infection with HTLV III is certainly AIDS, it cannot be assumed that all infections with this virus will necessarily lead to this disease, although the possibility cannot be ruled out.<sup>69</sup>

**10.48** There was now a realistic official assessment of the probability of a growing epidemic in the UK. On 16 January 1985, the Department for Health and Social Security (DHSS), jointly with the Health and Safety Executive, issued a press release: 'AIDS guidelines for clinical and laboratory staff'.<sup>70</sup> The press release noted the publication of the Interim Guidelines and stated that a review of the measures recommended would be undertaken within the next 12 months to take into account any new knowledge or understanding of AIDS.

**10.49** On 25 February 1985 Mr John MacKay, Under-Secretary of State for Scotland, told Parliament that there had been four cases of AIDS reported in Scotland.<sup>71</sup> One patient had died in 1982 and one in 1984. In addition a patient ordinarily resident in England had died in Scotland in 1984.

**10.50** Over the next few months there was an explosion of published material. Typical examples are referred to in the Preliminary Report.<sup>72</sup>

### *Official statements*

**10.51** Official statements were distributed. On 1 April 1985, the Chief Medical Officer (CMO) for Scotland issued a circular letter to Chief Administrative Medical Officers and community medicine specialists,<sup>73</sup> together with a leaflet entitled 'Some Facts about AIDS'<sup>74</sup> which was then available for distribution. It was produced by the Health Education Council and reprinted for the Scottish Health Education Group. This was followed, on 17 May 1985, by a letter from the Deputy Chief Medical Officer (DCMO) to all doctors.<sup>75</sup> The papers sent with the letter contained a further summary of the state of knowledge of the UK government at the time entitled 'AIDS – general information for doctors', dated May 1985, and a paper dated 22 February 1985 prepared by the Communicable Disease Surveillance Centre in London giving a detailed account of the epidemiology of the condition.<sup>76</sup>

<sup>69</sup> Ibid, [DHF.001.6071] at 6077

<sup>70</sup> Press release: 'AIDS guidelines for clinical and laboratory staff' [SNB.001.0124]

<sup>71</sup> Written Parliamentary Answer [DHF.001.9389]

<sup>72</sup> See, for example: Madhok 'HTLV III antibody in sequential plasma samples: from haemophiliacs 1974-1984' *The Lancet*, 1985; 325:524-525 [LIT.001.1673]; See also the Preliminary Report, paragraphs 8.146 and 8.147

<sup>73</sup> Letter from the CMO dated 1 April 1985 [SNB.004.9328]

<sup>74</sup> Leaflet 'Some Facts About AIDS' [SNB.004.9329]

<sup>75</sup> Letter from the DCMO dated 17 May 1985 [SGH.004.6581]

<sup>76</sup> 'AIDS – general information for doctors' [SGH.004.6582]; CDSC Epidemiology Paper [SNB.004.9642]

**10.52** The paper dated 22 February 1985 and prepared by the Communicable Disease Surveillance Centre stated:

[T]here is a wide spectrum of clinical states associated with HTLV3 infection ranging from healthy antibody-negative persons to patients with fully developed AIDS. It seems probable that only a very few of the infected persons become ill ....

....

Tests for antibodies to HTLV3 have been developed but these are not tests for AIDS and are difficult to interpret.<sup>77</sup>

**10.53** The paper 'AIDS – general information for doctors' reiterated the established criteria for reporting AIDS, following the US CDC definition,<sup>78</sup> and noted that they had been accepted by other countries and by the World Health Organization (WHO). It stated that, by the end of February 1985, 132 cases of AIDS had been reported within the UK and that there had been 58 deaths. Data indicated that three haemophilia patients were included and that there were no cases of infected blood transfusion recipients. The covering 'Dear doctor' letter from the DCMO gave more up-to-date data: there were four cases of AIDS registered 'to date' in Scotland and 159 cases in the UK. Doctors who had patients with AIDS under their care were invited to assist in the maintenance of a register by reporting in strict confidence to the Communicable Diseases (Scotland) Unit in Glasgow.

**10.54** Further observations in the UK government's general information for doctors included:

The risk of infection as a result of blood transfusion is extremely low. Infection with HTLV-III has occurred as a result of treatment with Factor VIII and Factor IX. Heat treated Factor VIII is now available and in use and is likely to eliminate the risk of transmission.<sup>79</sup>

And:

HTLV-III infection is already widespread in certain groups at risk (e.g. in homosexuals with multiple sexual partners and in haemophiliacs). Estimates vary as to what percentage of infected individuals will ultimately develop AIDS, but it may be in the order of 10 per cent.<sup>80</sup>

**10.55** The prevailing view, as published, remained that HTLV-III infection was unlikely to progress to AIDS in the majority of cases but that the risk to haemophilia patients, and a lesser risk to transfusion patients generally, was recognised. There appears to have been a conscious effort to avoid panic reactions while providing doctors generally with information and advice about AIDS and HTLV-III infection that was not otherwise available in textbooks at that stage.

**10.56** Some experts thought that there were aspects of AIDS that were not adequately monitored in the UK. The Preliminary Report set out details of arguments advanced by Professor Julian Peto, Professor of Epidemiology at the Institute for Cancer Research, in

---

<sup>77</sup> CDSC Epidemiology Paper [SNB.004.9642] at 9643

<sup>78</sup> See paragraph 10.1 above.

<sup>79</sup> 'AIDS – general information for doctors' [SGH.004.6582] at 6586

<sup>80</sup> *Ibid.*, [SGH.004.6582] at 6589

a letter dated 20 May 1985 circulated to members of the Medical Research Council.<sup>81</sup> He thought that AIDS might already be 'catastrophic' for haemophilia patients and for homosexual men in London. His attached paper<sup>82</sup> was a plea for further research but it presented a more pessimistic projection of future progression of the disease than the official government position. Professor Peto suggested that many and possibly the majority of seropositive individuals might eventually die of AIDS. Even the fact that AIDS was always, or almost always, fatal was still not universally appreciated at this time as only half the individuals diagnosed with the disease had so far died. It was thought by Professor Peto that only a minority, if any, of the general population might be capable of mounting an effective immune response to initial infection and it seemed to him likely that the chronic infection that ensued constituted a permanent infective carrier state.

### *The Edinburgh Cohort revisited*

**10.57** On 23 May 1985, Professor Ludlam sent Dr Perry a copy of the final draft of the RIE study of the Edinburgh Cohort,<sup>83</sup> later published in *The Lancet* on 3 August 1985.<sup>84</sup> The introduction to the published paper reported as background that the virus HTLV-III/LAV was the most likely cause of AIDS and that tests carried out on stored serum samples from haemophilia patients showed that HTLV-III antibodies were first detectable in the USA in 1978 and in the UK no later than 1979. The summary stated:

Fifteen haemophiliac patients acquired antibodies to [HTLV-III] during 1984. One batch of factor VIII concentrate given to all these patients is presumed to be the cause of the seroconversion. A further eighteen patients who received the same batch did not seroconvert .... Ten other patients received a batch of factor IX concentrate from the same donor plasma; none of these patients seroconverted.

**10.58** The article further commented in its introduction:

In contrast to haemophiliacs elsewhere in the UK, almost all patients attending the Edinburgh Haemophilia Centre have received factor VIII and IX concentrates prepared exclusively from locally collected plasma by the Scottish National Blood Transfusion Service (SNBTS). Until recently there were no reported cases of AIDS in Scotland and it therefore seemed possible that our patients might not be exposed to HTLV-III ...

As part of the continuing assessment of our haemophiliacs, we have now observed that sixteen of our patients acquired anti-HTLVIII during 1984; all but one of these patients had received a common batch of SNBTS factor VIII concentrate.

**10.59** The study discussed 34 patients with Haemophilia A and eight patients with Haemophilia B. It reported their treatment histories and noted that samples dated up to early 1984 were all negative on testing for anti-HTLV-III. None of the infected patients was known to have risk factors for developing antibodies to HTLV-III other than replacement therapy.

<sup>81</sup> Preliminary Report, para 8.153; Professor Peto's Letter [DHF.002.5498]

<sup>82</sup> Professor Peto's paper [DHF.002.5499]

<sup>83</sup> Letter from Dr Ludlam to Dr Perry [SNF.001.3271]; Final Draft of Paper [SNF.001.3272]

<sup>84</sup> Ludlam, C *et al* 'HTLV-III infection in seronegative haemophiliacs after transfusion of factor VIII' *The Lancet*, 1985; 326:233-236 [LIT.001.1669] Preliminary Report, para 8.154

**10.60** The paper set out the results in some technical detail. In summary, the discussion noted:

- The prevalence of anti-HTLV-III in Scotland among haemophilia patients at the beginning of 1984 was relatively low and where it occurred could be attributed to occasional use of commercial blood products. In contrast, in some places prevalence had risen to over 90%.
- One specific batch had probably caused the infection in the Edinburgh Cohort: a definitive investigation would have to await a reliable test of infectivity. All but one of the 16 patients with Haemophilia A who had developed anti-HTLV-III had received the batch between March and May 1984.
- The risk of developing HTLV-III was a function of the recipient's helper/suppressor cell ratio,<sup>85</sup> the number of transfused vials of presumed infected Factor VIII and the total annual consumption of Factor VIII.
- If the study were otherwise correct in its conclusions, half of the patients who received the single suspect batch did and half did not develop antibodies to HTLV-III.
- Patients who received Factor IX prepared from the same pool were known. None demonstrated seroconversion when tested up to four months after infusion.

**10.61** The presumed infective batch was manufactured in November 1983 from plasma collected in the autumn of the same year. Following the reports of product infectivity, attempts were made to identify the specific donation(s) which led to the product being infective but these were unsuccessful. The paper noted that the PFC had developed a programme to study possible methods of eliminating the transmission of viral infections by blood factor concentrates. The expertise developed had been put immediately into effect, following the finding of HTLV-III antibodies in Scottish patients.

### *The reality of risk for recipients of blood and blood products*

**10.62** The AIDS Information and Advisory Group at the Glasgow Royal Infirmary (GRI) met on 31 May 1985.<sup>86</sup> In common with others, they recognised the need for further research. In the west of Scotland, 16% of haemophilia patients were HTLV-III antibody positive.<sup>87</sup> All had, in retrospect, seroconverted between 1981 and 1983. The minutes of the meeting noted that the Regional Reference Laboratory was using the 'Abbott' kit,<sup>88</sup> confirmed by immunofluorescence testing, for HTLV-III antibody testing, with reference to Dr Tedder in London in the event of inconsistent results. Dr Robert Crawford, a Consultant at the West of Scotland Blood Transfusion Service, reported that the national HTLV-III test evaluation was progressing. The aim was to test all blood donations at major regional blood transfusion centres, with the particular aim of protecting the higher-risk pooled products, rather than the low-risk single-donor products, from infected donations. It was stated that arrangements should be made to counsel blood donors found to be HTLV-III antibody positive.

<sup>85</sup> Helper/suppressor ratios are discussed in Chapter 11, *HIV/AIDS Aetiology*, paragraph 11.86

<sup>86</sup> Minutes of AIDS Information and Advisory Group, 31 May 1985 [SNB.004.9656]; Preliminary Report, para 8.155

<sup>87</sup> By 1991 the rate of infection in treated haemophilia patients in Edinburgh was said to be 25%: Cuthbert et al, 'Immunological studies in HIV seronegative haemophiliacs' *British Journal of Haematology*, 1991; 80:364–9 [PEN.012.0405]

<sup>88</sup> The testing kit developed by Abbott Diagnostics in the USA.

**10.63** The focus was changing away from discussing whether there actually was a risk of transmission of infection: interest was now focused on the response to the reality of the risk for recipients of blood and blood products and the need for care of donors and patients. Inactivating virus contamination by heat-treatment was promoted as part of the response and Dr Crawford reported that the second generation of heat-treated Factor VIII concentrate was being clinically evaluated. Heat-treated Factor IX concentrate was still under development and had not been released for clinical evaluation at that stage.

**10.64** Government agencies continued to collect data. On 20 September 1985 a note to the Private Secretary of John MacKay, Under Secretary of State for Scotland, and copied to the offices of the Secretary of State, the CMO and other senior officials, provided data on the incidence of AIDS to the end of August.<sup>89</sup> There were said to be 206 cases in the UK, of which 114 individuals had died. The figures for Scotland were six cases and two deaths. Comparative figures to the end of February had been 132 cases in the UK, of which 58 had died, with Scotland having four cases and two deaths.

**10.65** On 26 September 1985, a press release was issued by the DHSS<sup>90</sup> and, in turn, a press release was drafted by the SHHD.<sup>91</sup> The SHHD press release was entitled 'Countering the Spread of AIDS in Scotland' and stated that, to that date, six people in Scotland had developed AIDS, of which two had died. The UK total was 206 cases of AIDS, of which 114 had died.

#### *The prevalence of HTLV-III antibody in haemophilia patients in the UK*

**10.66** There was by now growing interest in the prevalence of HTLV-III antibody in haemophilia patients in the UK.<sup>92</sup> The need for research had been anticipated and was now in hand. Dr Rizza and Miss Rosemary Spooner of the Oxford Haemophilia Centre contacted the 109 haemophilia centres in the UK requesting information on the antibody status of their patients and on 27 September 1985, the results were circulated.<sup>93</sup> Eighty-one centres provided data. Of the remaining 28, four replied that they could not cooperate because of confidentiality issues and three said that they would try to provide information later. The survey was destined to be less than comprehensive.

**10.67** At the time there were 4918 Haemophilia A patients, 896 Haemophilia B patients and 1725 von Willebrand's disease patients on the national haemophilia register. Of the 2970 Haemophilia A, Haemophilia B and von Willebrand's disease patients treated in the UK in 1984, 2525 had been tested.<sup>94</sup> The range of results as reported for those groups was as follows:

<sup>89</sup> Note to Mr MacKay and others [SGF.001.0831]

<sup>90</sup> DHSS Press Release: 'the fight against AIDS – more government money' [DHF.001.7916]; Preliminary Report, para 8.136

<sup>91</sup> SHHD Press Release [SGH.002.7072]

<sup>92</sup> Preliminary Report, para 8.164

<sup>93</sup> Interim Report on Survey of HTLVIII Antibody in Haemophiliacs in UK [SNB.001.7593]

<sup>94</sup> A total of 2570 patients were tested including carriers of Haemophilia A and B and other groups. Data from these cohorts (45) are not represented above.

**Table 10.1: UK Haemophilia AIDS Survey**

	Patients treated in 1984	Patients Tested for HTLV-III	% of Treated Patients Tested	Number HTLV-III Positive	% of Tested Patients Positive
Haemophilia A	2277	1994	88	873	44
Haemophilia B	391	316	81	20	6
von Willebrand's	302	215	71	11	5
<b>Total</b>	<b>2970</b>	<b>2525</b>	<b>85</b>	<b>904</b>	<b>36</b>

**10.68** In the case of severely affected Haemophilia A patients (defined for this purpose as having less than 2% Factor VIII)<sup>95</sup> the proportion testing positive for HTLV-III rose to 59%. The average proportion testing positive in the three groups combined was 36%.

**10.69** The age profile for severely affected haemophilia patients with HTLV-III antibodies (expressed as a percentage of the total numbers tested) was:

**Table 10.2: age profile for severely affected haemophilia patients with HTLV-III antibodies**

Age	0 - 5	5 - 9	10 - 14	15 - 19	20 - 29	30 - 39	40 - 49	50 - 59	60 - 69	70 +
Haem A	6	32	68	65	68	65	61	51	34	20
Haem B	0	0	0	9	15	3	6	14	20	0

**10.70** The highest percentages according to age groups were in those aged 10–14 years and those aged 20–29.

**10.71** On the basis of the data collected, and assuming that those patients not yet tested were at the same risk as those already tested, the authors of the report predicted that if all children with Haemophilia A up to the age of 19 (865 children) were to be tested, 320 patients (37%) might be expected to be HTLV-III positive.<sup>96</sup>

**10.72** Tables prepared by Dr Craske dated 1 October 1985 gave data on cases of AIDS-related diseases reported to the Oxford Haemophilia Centre.<sup>97</sup> A total of 67 cases in patients with Haemophilia A or von Willebrand's disease had been reported along with three cases in patients with Haemophilia B.

<sup>95</sup> See Chapter 2, *Patients at Risk*, paragraph 2.26 for discussion of the categorisation of haemophilia into 'mild', 'moderate' and 'severe' categories.

<sup>96</sup> Interim Report on Survey of HTLVIII Antibody in Haemophiliacs in UK [SNB.001.7593] at 7596

<sup>97</sup> Haemophilia AIDS Group – Cases of AIDS Related Diseases Notified to Oxford 1 October 1985 – Table 1 [SNF.001.1106]

**10.73** The diseases reported were:

**Table 10.3: Cases of AIDS-related diseases, October 1985**

Syndrome	Haemophilia A		Haemophilia B	
	Total	Deaths	Total	Deaths
AIDS: <i>Pneumocystis carinii</i> pneumonia	7	6		
AIDS: opportunistic infections	3	2	1	1
'AIDS Related Complex' (the patient who died committed suicide)	15	1		
Other syndromes	3		1	
Thrombocytopenia	20	1		
Persistent Generalised Lymphadenopathy	12		1	
Glandular fever-like syndrome	7			

**10.74** Seventy-five family contacts were also tested and four partners were found to be anti-HTLV-III positive.<sup>98</sup>

**10.75** On 28 November 1985, an internal DHSS memorandum was sent to the Chief Medical Officer for England and Wales.<sup>99</sup> It commented on some hearsay evidence that haemophilia patients were seroconverting to become anti-HTLV-III positive despite being given heat-treated Factor VIII. This became an issue for discussion in 1986. If true, it would have indicated that the epidemic was less likely to be contained by the existing production technology employed in the manufacture of blood products for therapeutic use.

## 1986

### *Further information on prevalence*

**10.76** Additional information on prevalence was gathered. On 7 February 1986 there was a meeting to discuss the virological aspects of the safety of blood products at the National Institute of Biological Standards and Control (NIBSC).<sup>100</sup> At the meeting, Professor Forbes raised the issue of seroconversion after treatment with heat-treated concentrates, with particular reference to three specific patients.<sup>101</sup> The question was to attract attention for some time and cast some doubt on the effectiveness of the PFC's heat-treatment of Factor VIII concentrate. It was dealt with in official correspondence in February and March.<sup>102</sup> So far as concerns the spread of the epidemic, it was eventually shown to be a false trail. A general consensus was reached that the seroconversions of the three patients were related to previous treatment with untreated material of either commercial or NHS origin.

**10.77** The survey data now covered 2609 UK patients from 81 haemophilia centres. Of Haemophilia A patients, 46% were positive for HTLV-III antibody. For Haemophilia B patients and von Willebrand's disease patients the figures were 6% and 5% respectively.

<sup>99</sup> Memo to CMO [DHF.001.8523]

<sup>100</sup> Minutes of a meeting on the Virological Aspects of the Safety of Blood Products, held at the NIBSC on February 7th, 1986 [SNB.005.1495]; Preliminary Report, para 8.168

<sup>101</sup> Ibid [SNB.005.1495] at 1501. This was the issue raised with the CMO, England and Wales, on 28 November 1985, noted above.

<sup>102</sup> Dr Perry's letter [SNB.004.7776]; Dr Forbes' letter [SNB.004.7732]; Preliminary Report, para 8.171

**10.78** The source of infection in patients with coagulation defects continued to be debated. In discussion at the meeting on 7 February, Professor Tedder reported that, tests of stored samples dating from 1978 to 1984 showed that seropositivity rose rapidly from 33% in 1980 to 64% in 1982 in the case of patients who had received commercial concentrates. In the case of patients who had received NHS concentrates, samples were seronegative until 1982. Between 1983 and 1984 seropositivity rose from 1% to 11%. These rates were considerably higher than those indicated by the data on AIDS cases reported on CDC criteria down to 1984 which were discussed in Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*. The Director of the NIBSC, Geoffrey Schild, asked if anyone knew the reasons for the low incidence of clinical AIDS (around 1%) in seropositive haemophilia patients. Dr Craske and Professor Forbes said that the true incidence of AIDS was probably much higher, due to a tendency to suppress reporting.<sup>103</sup> It has to be remembered, however, that until Professor Tedder's tests were applied data were collected only on cases meeting the CDC definition of AIDS. Under-reporting of AIDS may have been a factor but, with the benefit of hindsight, long periods of asymptomatic infection with HIV must also have contributed to the difference as the CDC criteria required the presence of intractable AIDS-associated disease for a case to be 'confirmed' as one of AIDS. The natural history of the disease was still not understood.

**10.79** At a meeting of the SNBTS Directors on 25 March 1986, it was reported that the transfusion service was concentrating on following up patients who had received donations known to have been contaminated by HTLV-III.<sup>104</sup> Professor Tedder intended to study the epidemiology of infected donors and all recipients of implicated blood and blood products, retrospectively for five years. It is not clear that these studies progressed or produced meaningful results but they reflected growing appreciation of the need for better understanding of the natural history of the disease.

**10.80** At successive conferences, new data on HIV prevalence were reported with reference to different cohorts and with inconsistent and irreconcilable results.

**10.81** At a conference on AIDS held in Newcastle between 11 and 13 February 1986 and sponsored by the Haemophilia Society, Professor Tedder commented that the small number of seroconversions following the use of heat-treated Factor VIII concentrates was due to 'a long delay in the latent phase'. On this view, transmission of infection as a result of treatment had occurred but diagnoses had been made only after the change of treatment regime to include heat-treated products. The natural history of HIV infection was becoming more clearly understood and AIDS was said to present a significant problem for the future.<sup>105</sup> There were estimated to be about 20,000 positive individuals in the UK, spread among four groups. Dr Foster's report summarised the information available<sup>106</sup> as follows:

<sup>103</sup> Minutes of a Meeting on the Virological Aspects of the Safety of Blood Products, held at the NIBSC on February 7th, 1986 [SNB.005.1495] at 1502

<sup>104</sup> Minutes of a Directors Meeting Held in the HQ Unit on 25 March 1986 [SNF.001.0135] at 0138-9; Preliminary Report, para 8.173

<sup>105</sup> Report of AIDS Conference, 11-13 February 1986 [SNF.001.4215] at 4216; Preliminary Report, para 8.169

<sup>106</sup> Ibid, [SNF.001.4215] at 4218

**Table 10.4: UK Situation by February 1986**

Group	Total Number	% Antibody Positive	Trend
Haemophiliacs	4000	25%	Down
Blood recipients	1,000,000	0.006%	Down
IV drug users	20,000	5%	Up
Gay people	500,000	3%	Up

**10.82** The percentage of antibody positive haemophilia patients was significantly lower than that reported by Dr Rizza and Miss Spooner above.

**10.83** Dr Peter Jones, Director of the Newcastle Haemophilia Centre, also spoke specifically about the incidence in patients with haemophilia: he estimated, extrapolating from the limited data available, that 1200 UK haemophilia patients would already have seroconverted. In relation to treatment, he said that of those who had been treated with cryoprecipitate only, 1% tested positive for the virus; of those treated with NHS concentrate only, 10% were positive; and of those treated with commercial concentrate only, 45% had tested positive. His basic data were not consistent with the data collected by Dr Rizza and Miss Spooner but referred to a cohort of similar size and with less variance than the data reported by Dr Foster.<sup>107</sup>

**10.84** At the 19th Congress of the International Society of Blood Transfusion in Sydney between 11 and 16 May 1986, the association of AIDS with the use of blood products was discussed.<sup>108</sup> Participants reported their experiences. There were differences both internationally and within and among regions.

**10.85** Professor Arthur Bloom reported that 43 out of 153 haemophilia patients in Cardiff (28%) had seroconverted, compared with the rate for the UK as a whole, which he said was 44%. He said that the incidence of transfusion-associated AIDS in Australia was 10 times greater than in the UK. He also commented on the timescale of seroconversions of Haemophilia A and B patients. The time from exposure to seroconversion ranged from six days to one year and the mean timescale for developing 'full blown' AIDS was three years. He suggested that haemophilia patients might be 'lagging behind' other high-risk groups in developing AIDS.<sup>109</sup>

**10.86** Dr Jones reported experience among people with haemophilia in Newcastle. There were eight confirmed cases of clinical AIDS and four awaiting confirmation, an incidence of eight to ten per cent.<sup>110</sup> In the report, written by Dr Foster, Dr Jones is said to have claimed that the degree and type of treatment in Newcastle was no different to many other centres and he was unable to postulate any reason why haemophilia patients in Newcastle should have been affected so differently. Other reports on infection among haemophilia patients, from the USA, Australia and France, gave comparative data. Dr Bruce Evatt, CDC, reported on the incidence of seropositivity in the USA. As already noted<sup>111</sup> prevalence values were 74% in people with Haemophilia A and 35% in people with Haemophilia B, with 15%

<sup>107</sup> Report of AIDS Conference, 11-13 February 1986 [SNF.001.4215] at 4220. Dr Jones had data from 2025 patients compared to the 2525 reviewed by the Oxford study.

<sup>108</sup> Dr Foster's report of the Congress [SNB.008.6547]

<sup>110</sup> Ibid [SNB.008.6547]

<sup>111</sup> Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*, at paragraph 9.65.

of 'haemophilia wives' also seropositive and with the seroconversion rate still increasing. A 12-month French study reported by Professor Jean-Pierre Allain showed 58% seroconversion in the patients included. Dr Roger Garsia from Australia found 45% seroconversions among the 161 patients studied. The Congress also discussed the incidence of seroconversion in non-haemophilia patients following treatment with blood products.<sup>112</sup>

**10.87** This was a wide-ranging conference in which doctors from around the world shared their experiences of the epidemic. It exposed the prevalence of AIDS and HIV antibody positivity over a number of countries. The advantage of heat treatment of products was a major topic. According to Dr Garsia, there had been no cases of seroconversion in Australia since the introduction of heat-treated products. Others, however, spoke of experiences of seroconversion following use of heated products. The Congress appears to have been exploratory in nature, with each participant contributing to the general understanding of the wider AIDS epidemic.

### *The European context*

**10.88** Between 28 and 31 May 1986, the Committee of Experts on Blood Transfusion and Immunohaematology met at Berne.<sup>113</sup> Much of the background material in the report was repeated in the Advisory Committee on Dangerous Pathogens (ACDP) guidelines issued in June and is dealt with in that context below.<sup>114</sup> The factual material set out the wider European understanding of the position at the time. It was observed that, prior to the screening of donated blood, many haemophilia patients had become infected, as had a few recipients of transfusions. It was said that these routes of infection had now been closed by a combination of measures – publicity to deter those in high-risk groups from donating blood, heat-treating blood products to inactivate any virus they might contain and testing all blood donations for antibody and discarding any that were found to be positive.

**10.89** The report tabulated data on: AIDS cases and deaths up to various dates in 1985 and 1986; screening of blood donations; information to and counselling of donors and follow-up of patients receiving blood from antibody-positive donors; cases of positive tests for the virus and of AIDS in patients with haemophilia; and treatment of haemophilia.<sup>115</sup> The information provided on UK non-haemophilia patients up to March 1986 was that there had been 342 cases of people infected with AIDS, of whom 172 had died. The data relating to Haemophilia A and B patients were derived from the Oxford study discussed above with some updating. The total population remained the same: 4918 people with Haemophilia A and 896 people with Haemophilia B. The position for UK haemophilia patients was set out as:<sup>116</sup>

<sup>116</sup> *Ibid* [SNB.004.8127] at 8136

**Table 10.5: Data on AIDS cases and deaths by 1986**

	Number of patients	Number treated	Anti-HTLV tested	Positive	%	Number with AIDS/ARC <sup>117</sup>
Haem A	4918	2277	2025	896	44	18/20
Haem B	896	391	324	20	6	3/0

**10.90** The percentages of patients testing positive had not changed and the numbers with AIDS or ARC remained broadly the same.

**10.91** By way of comparison, it was reported that:

The positive rate for anti-HTLV 3/LAV in patients suffering from Haemophilia A varied considerably from 4% in Belgium and 8% in Norway to over 90% in Malta and the USA. The usual level of positivity was between 35 and 60%. The low rate of positivity in Belgium and Norway could probably be attributed to the almost exclusive use of cryoprecipitates prepared from local donors.<sup>118</sup>

**10.92** It was further reported that, with a few exceptions, the positive anti-HTLV-III/LAV rate for patients with Haemophilia A was greater than that for Haemophilia B and that the incidence of AIDS and AIDS-related complex was also higher in Haemophilia A in most instances. Dr Albert Farrugia (Malta) suggested that the 95% incidence of anti-HTLV-III/LAV antibodies in Haemophilia A patients in Malta had almost certainly arisen because these patients had been exclusively treated with imported Factor VIII concentrate, whilst patients with Haemophilia B had been treated with Factor IX concentrate obtained from European voluntary donors.<sup>119</sup>

**10.93** In June 1986, the ACDP issued 'Revised Guidelines' on LAV/HTLV-III.<sup>120</sup> It was reported that the number of cases of AIDS (in Europe) continued to double every 6 to 12 months. Detailed figures were provided for reported cases and estimated rates per million of population in 21 European countries including the UK.<sup>121</sup>

**10.94** Rates of infection in those European countries supplying figures ranged from 1.0 per million of population (Greece) to 11.9 (Belgium).<sup>122</sup> The figure for the UK was 4.0 per million. Globally, it was stated:

In certain parts of Africa where LAV/HTLV III has probably been present longer than in the USA, small surveys have detected evidence of infection in as much as a fifth of the sexually active population and in some parts of the USA it now seems that a majority of male homosexuals are infected. It is not assumed that this will necessarily happen in the UK but it has to be recorded that such levels of infection have been observed elsewhere.<sup>123</sup>

<sup>117</sup> AIDS related complex

<sup>122</sup> Advisory Committee on Dangerous Pathogens (ACDP) – Revised Guidelines on LAV-HTLV III – The Causative Agent of AIDS [DHF.002.1456] at 1465. NB Several reported 0% infection rates (Czechoslovakia, Hungary, Iceland, Poland, USSR).

<sup>123</sup> Ibid [DHF.002.1456] at 1464-65

**10.95** The general hazard and risk statement commented:

[T]here are very serious consequences for a proportion of those infected, although not all will necessarily develop AIDS, which to date has invariably been a fatal disease. For this reason the intrinsic hazard of infection should not be under-estimated.<sup>124</sup>

**10.96** By this stage, the likelihood of patients having developed antibodies to HIV from blood products produced prior to the introduction of heat-treatment was understood to be high, in severely affected Haemophilia A patients in particular. It was also appreciated that AIDS was a fatal illness, although the risk of progression to AIDS was still underestimated. The natural history of untreated HIV infection was still not well understood.

***United Kingdom data updated***

**10.97** On 10 September 1986, Dr Craske issued an update on a retrospective study of HIV-related illness.<sup>125</sup> The data were incomplete: a second HIV antibody survey was in hand. By the date of the report, returns to the Oxford Centre in 1985 had identified eight batches of NHS Factor VIII and two of Factor IX that had been associated with either an anti-HIV positive donor or a donor who later developed HIV-related illness. Evidence of transmission had been identified in five of the Factor VIII batches, two were possibly associated with transmission, and there was no information on the remaining batch. There was evidence of transmission in one batch of Factor IX and information was awaited on the other batch. Quantification aside, the association between NHS factor products and the transmission of infection was clear.

**10.98** The report narrated:

The total number of patients reported to Oxford with HIV related illness by 22.4.86 was 109. This was 12.9% of the total antibody positive patients identified in the Survey in August 1985 (896) .... The number of AIDS cases reported of which 15 have died is 23. Eighteen cases are known to the Communicable Disease Surveillance Centre .... Two of these had not been notified to Oxford so that the total may come to 25.<sup>126</sup>

**10.99** The comparative number of patients with AIDS or AIDS-related conditions in the August 1985 survey had been 38. In September 1986, 109 cases were listed under three categories: (i) 'AIDS', comprising PCP (15), opportunistic infection (8) and AIDS related complex (20); (ii) 'unclassified' comprising abdominal lymphoma (1) and (iii) 'other syndromes,' comprising thrombocytopenia (28), purpura (5), PGL (30) acute glandular fever (10) and encephalopathy (2).<sup>127</sup>

**10.100** The paper stated that a significant number of HIV-infected persons would continue to develop AIDS-related illness over a period of years, despite the efficacy of heat-treated Factor VIII and Factor IX in preventing further patients being infected.<sup>128</sup> The

<sup>124</sup> Ibid [DHF.002.1456] at 1468; Preliminary Report, para 8.186

<sup>125</sup> Update on HIV Related Illness – September 1986 [SNF.001.1114]; Preliminary Report, para 8.189

<sup>126</sup> Update on HIV Related Illness – September 1986 [SNF.001.1114]. This appears to relate to Haemophilia A patients only: 896, the figure used in calculation, was the number of such patients who were antibody positive as at March 1986. The change of terminology within the papers from AIDS-related to HIV-related does not appear material in view of the specification of diseases given.

<sup>127</sup> Update on HIV Related Illness – September 1986 [SNF.001.1114] at 1116

<sup>128</sup> Ibid [SNF.001.1114] at 1115

small proportion of Haemophilia B patients so far infected with HIV was said to be partly accounted for by a lower contamination rate of Factor IX concentrate as compared with Factor VIII. This was said to be confirmed by independent observations of the Edinburgh Cohort.<sup>129</sup>

**10.101** Dr Craske advised that further study was necessary. He proposed that the next step in research should be to identify patients who were HIV-positive post-exposure and to increase the cohort for study to at least 30 or 40 patients. These patients would be followed up every six months in their usual review clinic. He emphasised that only limited additional investigations would be necessary. Dr Craske was still encountering obstacles. He wrote:

For the past 6 months there has been a lot of natural concern regarding the confidentiality of data reported to the National Survey at Oxford. Arising from this there was a noticeable drop in the rate of case reporting early this year. This had increased again in recent months, but I think it is still important to emphasise that reporting is necessary to enable us to obtain information on the size of the problem; to establish the efficiency of preventative measures e.g. safety of heat treated factor VIII, and to identify new patterns of the disease associated in the HIV infection.<sup>130</sup>

**10.102** On 3 October 1986, Dr Rizza and Miss Spooner of the Oxford Haemophilia Centre distributed a further report on the incidence of anti-HIV in people with haemophilia in the UK.<sup>131</sup> In this survey, 84 out of a total of 109 haemophilia centres made returns. Confidentiality remained an issue. Thirteen centres which contributed data in 1985 failed to do so in 1986 and 14 centres which had not made returns in 1985 did return data in 1986. The report noted that this had to be borne in mind in comparing data. 40.48% of 2228 Haemophilia A patients, 6.74% of 386 Haemophilia B patients and 2.75% of 327 von Willebrand's disease patients were anti-HIV positive. Individuals present in both the 1985 and 1986 returns were 1707 Haemophilia A, 283 Haemophilia B and 161 von Willebrand's disease patients. The analysis of results by age group and severity of blood disorder showed a broadly similar pattern to the 1985 survey.

**10.103** However, this was not intended to be a sample survey; rather, it was an attempt at a total survey of the whole haemophilia population. Piecemeal returns, with significant gaps, necessarily undermined the reliability of the exercise and the resulting information distributed to UKHCDO members cannot be treated as presenting a complete and valid picture of the prevalence of infection.

**10.104** In Scotland, data on registered blood donors were shared by all regions. At a meeting of SNBTS Directors on 9 October 1986 the current status of HIV antibody-positive donations reported since screening was started was: Inverness one; Aberdeen none; Dundee three; Edinburgh eight; Glasgow two; Belfast two.<sup>132</sup> The next meeting of the SNBTS Directors was on 17 December. The current status of HIV antibody-positive donations reported at that meeting was: Inverness, one; Aberdeen, none; Dundee, three; Edinburgh, nine; Glasgow, six; and Belfast, two.<sup>133</sup>

<sup>133</sup> Minutes of Directors Meeting held on 17 December 1986 [SGF.001.0189] at 0190

**1987**

**10.105** The minutes of the meeting of SNBTS Directors held on 3 March 1987 noted that one further donor in Edinburgh had been found to be positive.<sup>134</sup>

**10.106** On 22 June 1987, the Scottish Office issued a press release.<sup>135</sup> The latest AIDS figures for Scotland up to the end of May 1987 reported a total of 20 AIDS cases, with 12 deaths; this included two haemophilia patients who had both died. The figure also included one recipient of whole blood and one recipient of a blood product,<sup>136</sup> both of whom had died. (The equivalent figures for the UK were 791 reported AIDS cases with 444 deaths; these included 31 haemophilia patients of whom 25 had died; one haemophilia patient, who was also an intravenous drug user, who had died; and six recipients of blood by transfusion in the UK, all of whom had died.)

**10.107** When the UK Haemophilia Centre Directors met in London on 25 September 1987, AIDS had become the leading cause of death in UK haemophilia patients.<sup>137</sup> A third national survey of anti-HIV among haemophilia patients was under way. Three new patients had been reported as being seropositive in 1987. Amongst 314 sexual partners of anti-HIV seropositive haemophilia patients who had been treated, 18 (5.7%) had been found to be positive. Dr Craske commented that this compared with rates of up to 15% in the USA.

**10.108** In October 1987, a table in the journal *International Plasma News* showed the percentages of HIV seroconversion among haemophilia patients in eight European geographical areas and in Canada. Scotland had the lowest percentage, at 15%; the 'UK' figure (presumably England and Wales) was 46%; Canada and Spain were 69%. For Sweden, Italy, France, West Germany and Denmark, the values ranged from 31% to 60% and averaged 50%.<sup>138</sup>

**10.109** At the end of the year there was renewed discussion on the association between the use of heat-treated Factor VIII concentrate and HIV seroconversions in 'naïve' (otherwise 'virgin' or 'previously untreated') haemophilia patients. On 21 December 1987, following a telephone conversation with Dr Dale Lawrence of the CDC, Professor Bloom circulated information to haemophilia directors about experience in Canada.<sup>139</sup> There had been six initial seroconversions in the period from spring to summer 1987. The products used included dry-heated material developed by Cutter (heated at 68°C for 72 hours) and Armour (heated at 60°C for 30 hours) and possibly others. Canadian research implicated the manufacture of the Armour product and Travenol and production and distribution had been stopped.<sup>140</sup> Armour Factor VIII had been implicated in transmission in the USA and West Germany. The company had withdrawn its product in the USA. Professor Bloom noted that the CDC was convening an emergency meeting of manufacturers and haemophilia doctors in Atlanta on 11 January 1988. He commented that BPL's product (dry heated at 80°C for 72 hours) was 'in the air', and was to be discussed, with all of

the information, in the February meetings of the UKHCDO.<sup>141</sup> Product specification, and particularly heat-treating protocols, was entering into the discussion of factors influencing the development of the epidemic.

### 1988 and beyond

**10.110** In and after 1988, intelligence on the prevalence of HIV in the UK and the risks of progression to AIDS continued to be published and Parliament was updated on the developing position. For example, in a Parliamentary answer on 21 December 1989, it was stated that there had been 76 HIV-positive haemophilia patients and 12 non-haemophiliac HIV-positive recipients of blood or blood products in Scotland.<sup>142</sup> By the end of February 1990, the total number of haemophilia patients with AIDS in the UK who had died was 118.<sup>143</sup> In 1990 there was a report on patients with haemophilia in Edinburgh who had acquired HIV from commercial concentrates.<sup>144</sup> There was highly technical Scottish research into factors possibly indicating that an individual was at increased risk of swiftly progressing to full-blown AIDS.<sup>145</sup> The Edinburgh Cohort provided a particular focus for research and comment.

### The Edinburgh Cohort: developing knowledge

**10.111** At the time of the recall of batch 023110090, no chemical or biological test was carried out to ascertain whether it was infective. Dr Perry doubted whether there was a test available that could have been used. He said that those assays 'simply didn't exist'<sup>146</sup> and that the test used by Professor Tedder was not validated for patient samples, let alone as part of a pharmaceutical evaluation process.<sup>147</sup> The first testing on batch 023110090 by SNBTS was performed in 1985 using a commercial assay. This was a first-generation antibody test and the result was negative. This early version of the test was, however, unable to pick up low levels of antibodies in samples tested.<sup>148</sup>

**10.112** Between 1985 and 1986 further tests were carried out in a number of laboratories including the NIBSC. The tests then available would have been Enzyme-Linked Immunosorbent Assay (ELISA) tests,<sup>149</sup> all of which were looking for antibodies. None of the tests carried out gave any chemical or biochemical indicator that the batch contained an infectious virus or that it contained antibodies to a virus.<sup>150</sup> No test that was carried out indicated the presence of antibody to the virus until very much later.

**10.113** Dr Perry explained that after HIV screening was introduced in October 1985, all donors found positive were studied and their previous donations were traced and library samples, where available, of their donations were tested. These investigations established that none of those donations had been used to make up batch 023110090.<sup>151</sup>

## Publications

**10.114** An article in the *British Medical Journal (BMJ)* of 27 February 1988 set out results obtained from testing serum from the Cohort.<sup>152</sup> The narrative recorded that there were 18 patients affected and that 'infection was acquired from a single batch of Factor VIII during a short period starting in March 1984'. It was also suggested that:

[T]he low prevalence of HIV 1 infection in Scotland in 1983, when blood for the batch was collected, makes it probable that the batch was contaminated by a single donation.<sup>153</sup>

**10.115** It was reported that 32 patients had been transfused. Eighteen of those patients had undergone seroconversion.<sup>154</sup> Eight patients had developed symptoms before March 1987 ('the unwell group') and the other 10 remained asymptomatic in mid-1987. The symptoms included PGL, AIDS Related Complex (ARC) and AIDS. The authors tentatively suggested that there was a relationship between the amount of Factor VIII transfused and time to seroconversion. It was said that much of the variability in the course of infection was clearly the result of differences in susceptibility of the patients to infection.<sup>155</sup>

**10.116** The progression of disease in the Edinburgh Cohort received further attention in a paper written in 1988 by Professor Ludlam and colleagues.<sup>156</sup> The study period ran from early 1987 to mid-1988. By the end of that period two patients had died and only seven patients remained wholly asymptomatic. It was concluded that the amount of Factor VIII transfused did not influence clinical progression or the ability of doctors to isolate HIV from a patient's serum. It was also pointed out that:

Compared with other cohorts, the rate of morbidity and mortality in this cohort is relatively high with half the HIV seropositive patients having developed serious clinical complications within 4 years .... Thus in clinical terms, the implicated viral strain appears to be particularly virulent.<sup>157</sup>

**10.117** In an article published in *The Lancet* in 1988 by Dr C Michael Steel and others (including Professor Ludlam), the factual understanding of the source of infection at that time was set out:

It was ... established that a single batch of locally produced factor VIII had been contaminated with [HIV].... That batch was used by 32 previously seronegative patients between March and May, 1984.<sup>158</sup>

<sup>152</sup> Simmonds et al, 'HIV antigen and antibody detection: variable responses to infection in the Edinburgh haemophiliac cohort', *British Medical Journal*, 1988; 296:593-8 [LIT.001.0305]; Preliminary Report, paragraphs 8.206 and 8.207

As late as 1991, Dr Cuthbertson of the PFC was referring to there having been 16 seroconversions. Preliminary Report, para 8.221. Originally, 16 were reported but three further seroconversions were observed during follow-up between October and December 1984, with one of the original 16 being discounted as not having been infected by the implicated batch.

<sup>155</sup> Simmonds et al, 'HIV antigen and antibody detection: variable responses to infection in the Edinburgh haemophiliac cohort', *British Medical Journal*, 1988; 296:593-8 [LIT.001.0305]

<sup>156</sup> Cuthbert et al, 'Human immunodeficiency virus detection: correlation with clinical progression in the Edinburgh haemophiliac cohort' *British Journal of Haematology*, 1989; 72: 387-90 [LIT.001.0581]; Preliminary Report, para 8.211

<sup>157</sup> Ibid, [LIT.001.0581] at 0584. A possible link with a particular genetic feature in some of the affected individuals was explored in Steel et al, 'HLA haplotype A1 B8 DR3 as a risk factor for HIV-related disease' *The Lancet*, 1988; 1185-8, [LIT.001.0895], this was corroborated in later American and Australian studies. Kaslow et al, 'A1, Cw7, B8, DR3 HLA antigen combination associated with rapid decline of T-helper lymphocytes in HIV-1 infection' *The Lancet* 1990; 335: 927-30 [LIT.001.3825]

<sup>158</sup> CM Steel et al, 'HLA haplotype A1 B8 DR3 as a risk factor for HIV-related disease' *The Lancet*, 1988; 1185-8 [LIT.001.0895]

**10.118** By this stage, sophisticated methods of analysis of the evolutionary relationships among groups of organisms, such as HIV, had been developed. Typically presented as 'phylogenetic trees', the findings on analysis enabled the definition of genetic relationships among samples from several sources. In 1988, Professor Peter Simmonds and associates reported on phylogenetic analyses of two regions of the *env* gene, a component of the 'viral envelope' of HIV, in the Edinburgh Cohort. Sequences from most of the patients studied were grouped together on phylogenetic trees with common origins.<sup>159</sup>

**10.119** The study dealt with nine patients, eight of whom were members of the Cohort. Six were grouped closely on analysis and it was inferred that they were infected with HIV sequences from a single donor. It was suggested that three of the nine, including two members of the Cohort, may have been infected independently of the others at about the same time. The conclusion that one common batch of concentrate was implicated in the infection of the Cohort, reached previously on analysis of the transfusion records, was weakened. At that stage, however, 10 members of the Cohort had not been included in the study.

**10.120** A further study reflecting results obtained from examination of the Edinburgh Cohort was published in the *BMJ* in 1990.<sup>160</sup> The study did not identify any immunological variable or clinical characteristic which distinguished the patients who seroconverted from those who did not. It reported that, within the Edinburgh Cohort, the cumulative incidence of serious HIV-related disease was 55.5% at five years. A third member of the Cohort, a patient born in 1948, had died (in 1989).

**10.121** The understanding of the Cohort changed further with the publication in 1995 by Edward Holmes and others of further virological findings.<sup>161</sup> The study was aimed at clarifying the number and origins of the batches of Factor VIII involved in the HIV infection of the Edinburgh haemophilia patient population. It would be inappropriate in this report to enter into a detailed technical discussion of the studies carried out but some of the conclusions are material. With two exceptions, the patients studied were formed part of a single phylogenetic tree and fell into a single group. The patients were identified only by number. Patients 74 and 82 were the two patients distinguished in the 1988 study as possibly having been infected independently. In this 1995 study, patient 74 could not be separated from the main group with any confidence but there was good evidence that patient 82 was not a member of the main Cohort because his data suggested a close relationship with a patient, patient 80, who had never been exposed to batch 023110090 of the PFC's NY Factor VIII product and now appeared to have been infected by a different batch which patient 82 had also received. The similar viruses found in patients 82 and 80 must have been derived from a Factor VIII batch that they were known to have shared. Taking the results of their several studies together, the authors commented:

The most striking finding was that there are several distinct HIV variants circulating in Edinburgh. The haemophiliac patients appear to be divided into a number of distinct groups whose members were infected by at least two batches of contaminated factor VIII. This is particularly surprising since most of

<sup>159</sup> Balfe et al, 'Concurrent Evolution of Human Immunodeficiency Virus Type 1 in Patients Infected from the Same Source: Rate of Sequence Change and Low Frequency of Inactivating Mutations' *Journal of Virology*, 1990; 64:6221-6233 [PEN.012.1403]

<sup>160</sup> Cuthbert et al, 'Five year prospective study of HIV infection in the Edinburgh haemophilic cohort', *British Medical Journal*, 1990; 301:956-961 [LIT.001.0291]; Preliminary Report, para 8.2.12

<sup>161</sup> Holmes, EC et al 'The Molecular Epidemiology of Human Immunodeficiency Virus Type 1 in Edinburgh' *The Journal of Infectious Diseases* 1995; 171:45-53 [PEN.012.1679]

these patients seroconverted at about the same time (spring 1984) and were originally thought to have been infected after exposure to a single common batch.<sup>162</sup>

**10.122** After discussing the specific findings relating to patient 74, the paper stated:

Thus, there appear to have been 2 or 3 HIV-infected donors contributing to the local plasma pool at the time these batches were prepared (1983). This shows that there was substantial viral diversity during the early stages of the HIV epidemic in Scotland...<sup>163</sup>

**10.123** The same study discussed infected heterosexual and IVDU patients whose data had been analysed, and concluded:

The fact that the heterosexual and IVDU groups are some distance from the haemophiliac groups on all the phylogenetic trees shows that the HIV infections in these populations were independent and refutes suggestions the haemophiliacs could have been infected from the IVDU community.<sup>164</sup>

**10.124** Two potential sources of infection had been excluded. Further inferences were avoided. It appears from this work that the original conclusion, that there was a single donor source of infection transmitted to haemophilia patients by Factor VIII concentrates, was wrong.

### ***SNBTS investigations***

**10.125** On 25 January 1991, Dr Cuthbertson, then Quality Assurance Manager at the PFC, wrote to Professor Cash enclosing a final report, 'HIV Seroconversions related to SNBTS FVIII'.<sup>165</sup> This was an update of an earlier, interim report of 28 June 1986.<sup>166</sup> It reflected the information available to the PFC. The infection of 16 patients in Edinburgh was referred to, as was the infection of two patients in the West of Scotland, one of whom had seroconverted between 5 October 1984 and 25 October 1985. It was not possible to draw definitive conclusions as to the batches by which all these patients had been infected; batch 023110090 remained the main candidate for 15 of the 18 seroconversions but the other candidate batch(es) had not been identified.

**10.126** The report contained the following detail:

16 Haemophiliacs in the South-East of Scotland were found to have seroconverted to HIV at some stage during 1984. Fifteen of the 16 haemophiliacs received a common batch (023110090) and it has been concluded that this batch was infective.

Follow-up of West of Scotland haemophiliacs has revealed two patients receiving SNBTS FVIII who seroconverted in 1984 and 1985 respectively.

<sup>163</sup> Ibid [PEN.012.1679] at 1686

<sup>164</sup> Ibid [PEN.012.1679] at 1686

<sup>165</sup> Letter from Dr Cuthbertson to Professor Cash, 25 January 1991 [SNF.001.3564]; Report 'HIV Seroconversions Related to SNBTS FVIII' [SNB.001.1243]

<sup>166</sup> Interim Report [SNB.008.6427]

PATIENT 1

Incomplete details available as no written report ever received from reporting clinician (Dr Maddock [*sic* – Madhok], GRI).

Sample 1.7.82 Negative

Sample 12.12.83 Positive.

PATIENT 2

Seroconverted between 5.10.84 and 25.10.85. At least five years since previous Commercial FVIII

The batches of product received by the ... seroconverters are summarised in Table 1. The following should be noted:

- a. Neither of the West of Scotland patients received the batch (023110090) implicated in the South-East Scotland seroconversions.
- b. No batch is common to the two West of Scotland seroconversions.
- c. If SNBTS FVIII was responsible for each of the 18 seroconversions, then at least three infective batches must have been issued.<sup>167</sup>

**10.127** It is possible that there were four, not three, sources of infection. One of the South-East Scotland patients did not receive batch 023110090: there had to have been at least two sources of infection in that area. Two patients were infected in the West of Scotland but neither had received batch 023110090 and they did not receive batches in common with others. A manuscript note on a copy of Dr Cuthbertson's report recovered by the Inquiry questioned whether cryoprecipitate was a source. Cryoprecipitate was a potential alternative cause of limited spread infection in the West of Scotland where it was a popular therapeutic material. The probability of a single infection from a pooled product must be relatively low and must get lower as one multiplies examples. It is not possible for the Inquiry to identify definitively the source of infection in all cases. The discussion in the quoted report is in many respects inconclusive. It was noted at the end of Dr Cuthbertson's report that polymerase chain-reaction (PCR) studies were being carried out which might define more precisely the implicated batches but that the position remained uncertain, apart from in the Edinburgh Cohort.

**10.128** The final position on numerical data on the incidence of HIV infection and AIDS in those affected by blood, blood components and blood products, so far as uncovered by the Inquiry, is set out in Chapter 3, *Statistics*. For present purposes, it is sufficient to note that the final numbers consistently exceed the earlier estimates.

**10.129** At the date of the Inquiry's hearings, it appears that 15 of the 18 members of the Edinburgh Cohort had died.

### The Edinburgh Cohort: 2008 testing

#### *The history of batch 023110090*

**10.130** The history of batch 023110090 was investigated in great detail by the Inquiry. Although perhaps somewhat tangential to the progress of the AIDS epidemic in the period under discussion, it illustrates many of the difficulties confronting scientists at the time in conducting research into the association of AIDS with blood product therapy. In

<sup>167</sup> Report 'HIV Seroconversions Related to SNBTS FVIII' [SNB.001.1243]

addition there is some advantage in setting out the Inquiry's findings in the context of the foregoing discussion of the impact of the infected product on patients.

**10.131** Further investigations into the history of the infection of the Edinburgh Cohort took place in 2008. The preparation of batch 023110090 was studied in some detail and Dr Perry explained that the batch had a conventional history. Collection took place between June and October 1983, with plasma collected from each of the RTCs in Scotland. A total of 940 kilograms of plasma was collected from about 4000 donations. The plasma weight delivered to the PFC would have been recorded by each RTC.<sup>168</sup>

**10.132** At the PFC the plasma was first divided into intermediates or 'fractions', which were then stored frozen. When required they were taken out of inventory and entered into a specific batch manufacturing process, at which point a batch number was allocated. A record was kept to allow a trace back from the batch number of a product to the fraction.<sup>169</sup>

**10.133** Dr Perry explained that there were two forms of plasma record.<sup>170</sup> Boxes of 12 donations were bound together in groups of four for storage purposes and each group of four boxes was given a new identifier called a 'cold storage number'. The cold storage numbers for each group of four boxes were recorded in the batch record; these records were kept down to the box number. Each box had bar-coded labels. There was a clear link between the boxes and the donations from the RTC. Although the PFC could not itself identify individual donations, the RTCs had records which identified which plasma donations had gone into an individual box. From the record, 95 cold storage units were used to manufacture batch 023110090.<sup>171</sup>

**10.134** The batch record shows that the manufacturing process started on 7 November 1983 and produced 1070 vials of Factor VIII.<sup>172</sup> The batch record shows the number of vials placed at issue and entered into stock.<sup>173</sup> The product was cleared for issue on 10 February 1984 and the product clearance sheet showed when the batch was released for issue.<sup>174</sup> It was recorded that 1020 vials were sent to the South East of Scotland RTC and that fifty vials were supplied to the North East RTC in Aberdeen where they were held for the treatment of patients with haemophilia. A batch history sheet recorded the final quality release of the batch.<sup>175</sup> This document was used for stock control by PFC.<sup>176</sup>

### *Tracing the donations to batch 023110090*

**10.135** As the recording system was designed, the batch record allowed the SNBTS to trace the donations which had made up any particular batch. The cold storage numbers gave key references for the individual plasma boxes. The box number identified the RTC which supplied the box and the RTCs had records from which to identify the individual donations. From the individual donations it was then possible to identify the specific donors.<sup>177</sup>

**10.136** It was a deliberate policy to disable the PFC from identifying specific donors from its own records. This maintained a separation between the 'greater clinical environment' at the RTCs and the PFC, which was a pharmaceutical manufacturing plant.<sup>178</sup> Following a meeting on 6 November 1984, it was decided that repeat donations from the donors contributing to the implicated batch should be followed up.<sup>179</sup> That was done but none of the subsequent donations were found to be HIV-positive. Dr Perry did not know how many repeat or returning donors there were.<sup>180</sup>

**10.137** Subsequently, consideration was given to trying to test the donors of all 4000 donations.<sup>181</sup> Donation samples were available from about 50% of these donors. Having taken advice from Professor Tedder that 99.5% of the donors would be required for the exercise to be meaningful, this was not followed through and the proposal was not pursued.<sup>182</sup> Dr Perry referred to correspondence with Dr Tedder.<sup>183</sup> It was considered impossible to find the source of the donation in this way. Dr Perry accepted that as return donors came back the pool of potentially infective donors began to shrink. A chronology prepared by the SNBTS also set out the documents relevant to each event.<sup>184</sup>

### *2008 testing*

**10.138** Dr Perry explained that, by 2008, he personally was satisfied that batch 023110090 was the batch responsible for infecting most of Professor Ludlam's patients. He explained that after the present Inquiry was announced, the SNBTS anticipated that the question of the implicated batch would be investigated and they decided to look at the matter again. It turned out that the majority of the remaining vials of Factor VIII belonging to batch 090 had been destroyed in 1988. However a single vial was discovered in the laboratory of Professor Simmonds and it was sent for testing. The vial had been stored in uncontrolled conditions and there was concern that the contents would have deteriorated and that any virus would have degraded so that it was not detectable.<sup>185</sup>

**10.139** The samples were sent to the NIBSC on the authority of Professor Ian Franklin who was the National and Medical and Scientific Director of the SNBTS in 2008. The testing was done at the the NIBSC to extremely high standards. The vial was first tested by nucleic acid amplification (NAT) technology for the Hepatitis C virus (HCV), a PCR test for the presence of virus. Tests for HCV would provide a positive control if the assay was working. The SNBTS knew that products in 1983–84 and 1985 were likely to contain HCV, so if the test had come back negative for HCV this would have cast doubt over a negative result for the HIV test: it would have raised the inference that the product in the vial had degraded so much over the years that any virus originally in the vial had disappeared.

**10.140** In the event, the sample was positive for HCV RNA. The sample was negative, however, in a duplicate test for HIV-1 RNA by NAT, a standard commercial assay. The conclusion was that no HIV RNA could be found in the vial using that test.

<sup>178</sup> Day 38, page 59

<sup>181</sup> Letter from Dr McClelland to Dr Tedder, 28 November 1984 [PEN.012.1423]; 'Actions surrounding FVIII Batch 023110090' [PEN.016.1258] at 1266

<sup>182</sup> Dr Perry – Day 38, page 63

<sup>183</sup> Letter from Dr Tedder to Dr McClelland, 20 December 1984 [PEN.012.1424]

<sup>184</sup> 'Actions surrounding FVIII Batch 023110090' [PEN.016.1258] at 1270

<sup>185</sup> *Ibid* [PEN.016.1258] at 1263 and 1266; Day 38 pages 21–23

**10.141** Further 'in-house' tests were then done, with the result that there was evidence for the detection of HIV-1 RNA sequences at very low levels.<sup>186</sup> The in-house tests were very specialist, essentially research assays developed by expert virologists at the NIBSC. Dr Perry explained that the results suggested that the sample might contain a fragment of HIV RNA but that one could not be absolutely sure. The results were inconclusive because the research assay had not been subjected to the rigorous analysis needed for a routine test. However, it provided an indicative result of a fragment of RNA of HIV.<sup>187</sup>

**10.142** The NIBSC also carried out a combination test for antigen and antibody. This result was quite clear: the sample was reactive; HIV had been detected in the sample. As it was a 'combination test', it was not clear whether the sample was reactive for the antigen or the antibody and the precise meaning of the result was that there was either HIV antibody or HIV antigen in the sample.<sup>188</sup>

**10.143** Other tests using ELISAs came back negative and the Western Blot test was indeterminate. Dr Perry explained that these tests in 2008 were the first chemical and biological evidence that were in line with the epidemiological evidence from the patients in 1985.<sup>189</sup>

**10.144** The level of technological sophistication that has now enabled scientists to form these views about the infectivity of batch 023110090 had not been achieved at any time during the course of the AIDS epidemic among recipients of blood, blood components or blood products. The risk that the product presented to haemophilia patients could not have been identified at the time it was administered or investigated by chemical or biological assays after the infections were first diagnosed.

## Discussion

**10.145** This chapter has sought to trace evidence of the growing awareness among relevant practitioners, and in particular haemophilia clinicians, of the incidence and characteristics of HIV infection and AIDS-related diseases during the critical period up to and covering the introduction of effective technology for the treatment of factor concentrates, looking at the position in the world in general but with specific reference to the UK.

### *The Edinburgh Cohort*

**10.146** Particular attention has been paid to the Edinburgh Cohort. The discovery of HTLV-III infection in that group was not an isolated event: it happened in the context of the testing of samples from Haemophilia Centres throughout the UK using the Tedder/Weiss assay. However, the infection of the Cohort was distinguished by its scale; its concentrated impact on one regional centre; the fact that infection in the Scottish domestic product was unexpected; and in the extent and intensity of the investigation that followed. The immediate confusion following the discovery has been described. The last point is most instructive of contemporaneous understanding of the implications for manufacturers, transfusionists and haemophilia clinicians alike.

---

<sup>186</sup> 'Actions surrounding FVIII Batch 023110090' [PEN.016.1258] at 1283

<sup>187</sup> Day 38, pages 27–28

<sup>188</sup> Day 38, page 33

<sup>189</sup> Day 38, pages 28–29

**10.147** The timescale for withdrawal of batch 023110090 was short. From the records, Professor Ludlam ascertained on 29 or 30 October 1984 that the three original recipients of SNBTS concentrate had received material from that batch. The additional information from Professor Tedder was received on 2 November. Dr McClelland and Dr Boulton arranged for the withdrawal of the batch on 3 November. That was clearly the correct course of action.

**10.148** At the end of 1984, when the scale of infection in the Cohort was established, none of those involved in the SNBTS and in the haemophilia clinical service had the technological means to identify infective donations, or to assess the infectivity of blood products, or to find explanations for the course of events that unfolded. That continued to be the position.

**10.149** Dr Perry's view that it was a 'justifiable, though unproven assumption' that batch 023110090 was implicated was valid on the information available. It left open two alternatives, however: it remained possible, on the one hand, that the batch would prove not to be infective and it remained possible, on the other, that other batches were infective.

**10.150** The second of these possibilities raises the more significant questions. Unless investigations were to establish that all of the patients who were infected had received batch 023110090 and that none of those found to be infected had received SNBTS material from any other batch, it would have been logically indefensible to conclude that only the single batch was infected. By May 1985 it was known that one of Professor Ludlam's infected patients had not received material from batch 023110090. Source donations could not be identified and it was not possible by that route to limit the potential range of infected batches. Further, cases of infection were being identified at the same time in other parts of Scotland, and in particular in the Glasgow and West of Scotland Region.

**10.151** Technology was not sufficiently developed at the time of the recall of batch 023110090 to test it for infectivity. Initial testing in 1985 and 1986 found no chemical or biochemical indicator that the batch contained an infectious virus or that it contained antibodies to a virus. The SNBTS staff were not surprised by the negative test in 1985 because they knew that the tests were relatively insensitive and also thought that, if the infection derived from one donation, it would have been diluted by 4000 other donations. In addition, they did not know at the time how the HIV antibody partitioned during the fractionation process.<sup>190</sup>

**10.152** The testing of serum from patients reported in the *BMJ* in February 1988 led to the conclusion that 18 patients had acquired infection from a single batch and that the batch was probably contaminated by a single donation. At that stage there was some technological support for the inferences being drawn. Further scientific support was provided by Professor Simmonds and his associates in 1988. Whatever objections on strictly logical grounds might be taken to the initial inference that there was a common source of infection, there was now apparent scientific proof of the inference drawn from the information available at that time.

---

<sup>190</sup> Dr Perry – Day 38, pages 40–41

**10.153** It was to be 1995, however, before scientific evidence was published that there were two infective batches and contributions to the local plasma pool at the time by two or three HIV-infected donors. It was 2008 before something approaching scientific proof was available of at least anti-HIV in the sole remaining sample of batch 023110090. Dr Perry explained that, in his view, putting the 2008 test results together with the epidemiological evidence, batch 023110090 was 'probably infectious'. It would always fall short of absolute proof but he thought that there was a very strong probability that batch 023110090 was the correct batch to have identified as being responsible for the transmissions. As for the putative second infective batch, the possibility that this existed was only raised in 1995. By that point it was not possible to take the matter forward, the materials (including samples of any implicated batches) having long since been used or discarded.

**10.154** Details of HIV infection in the Edinburgh Cohort were widely reported. On the other hand, infections in some other affected groups were not. Dr Cuthbertson's final report of 25 January 1991 dealt with two infected West of Scotland patients only. As shown in Chapter 3, *Statistics*, the actual final picture would be seen to be quite different.

#### *Wider surveillance*

**10.155** Throughout the UK, there were deficiencies in the reporting of instances of infection. The picture that emerges from the account of Dr Craske's surveys reflects inconsistent and incomplete disclosure of relevant information by significant numbers of Haemophilia Centres and frustrating attempts to analyse the problems related to patients and their illnesses which led to the publication of partial information when, within the relatively small group of Centres involved, comprehensive sources of information were available. The wish to protect patients' confidential personal data is understandable, as is the belief that any level of disclosure would threaten confidentiality and with it the patient-doctor relationship. The stigma surrounding HIV infection was indiscriminate and damaging. The accounts of patients and their families in Chapters 4 and 5 are eloquent of the concerns felt by clinicians at the time. However, the outcome was unfortunate in the respect that, at the time, more comprehensive data might have influenced the approach to management of infected patients and accelerated the appreciation at government level of the risks presented.

**10.156** The Communicable Diseases Report Review, no 8, of 17 July 1992 stated:

The surveillance of the spread of HIV infection in the United Kingdom relies on the voluntary reporting of AIDS cases and HIV infected individuals, and on large-scale unlinked anonymous seroprevalence surveys. The distribution of currently reported cases by region and exposure category reflects the pattern of infection some years ago, because of the long incubation period of AIDS. New reports of HIV infected individuals identified through voluntary testing reflect current transmission patterns more closely but also depend on the numbers tested in each exposure category. Unlinked anonymous testing provides seroprevalence estimates for sentinel groups in the population but is limited by the extent to which epidemiological information can be related to the sera tested, and by the composition of groups that can be sampled. Moreover, serial seroprevalence data can only provide an indirect estimate of the incidence of new infections.

To extend national surveillance, a collaborative study was set up in 1986 by the PHLS to record relevant epidemiological information for both HIV antibody positive and negative individuals tested voluntarily in selected laboratories in England. The main objectives of the study are to enhance interpretation of data from HIV antibody positive reports, by providing information on the numbers tested according to exposure category; to provide an indication of seroprevalence in groups not sampled or categorised in the unlinked anonymous testing programme, and to provide direct estimates of incidence in selected high risk groups.<sup>191</sup>

**10.157** Eighteen laboratories in England were selected. The results obtained were tabulated:

**Table 10.6: Prevalence of HIV antibody by exposure category: October 1986–September 1991**

Exposure category	Males		Females	
	Number tested	Tested positive (%)	Number tested	Tested positive (%)
<b>Sexual intercourse</b>				
Homosexual/bisexual	17,685	1582 (8.9)	514	–
Heterosexual				
lived in/visited Africa	1970	134 (6.8)	1037	109 (10.5)
lived in/visited Americas	358	4 (1.1)	197	4 (2.0)
HIV positive partner	321	14 (4.4)	634	43 (6.8)
high risk partner	1798	10 (0.6)	5317	32 (0.6)
moderate risk partner	3427	5 (0.1)	3692	2 (0.1)
many partners	11,527	21 (0.2)	14,682	10 (0.07)
<b>Injecting drug use</b>	7031	184 (2.6)	3017	75 (2.5)
<b>Blood</b>				
Blood factor (eg, for haemophilia)	1022	60 (5.9)	141	–
Blood/tissue transfer (eg, transfusion)	1147	8 (0.7)	1483	9 (0.6)
<b>Mother to infant</b>	98	15 (15.3)	83	9 (10.8)
<b>Other</b>				
Multiple exposure categories	2059	92 (4.5)	745	18 (2.4)
Unspecified contact with HIV positive or at-risk person	2796	16 (0.6)	3320	12 (0.4)
Household Contact/nursing/needlestick/bite	440	–	405	–
<b>No reported risk</b>	46,331	15 (0.03)	28,039	8 (0.02)
Total	98,010	2160 (2.2)	63,306	331 (0.5)

**10.158** The table probably provides a reasonably reliable basis for comparison of the balance of infection among the groups sampled. Given its selective nature, however, it cannot present a picture of the incidence of disease generally. So far as transmission to NHS patients is concerned, it shows a very small rate of transmission by blood and tissue, as would have been expected after the introduction of anti-HIV testing. As noted above, the Oxford report of 3 October 1986 showed that 40.48% of 2228 Haemophilia A patients, 6.74% of 386 Haemophilia B patients and 2.75% of 327 von Willebrand's disease patients, almost all tested before heat-treatment of concentrates and screening of donors was commenced, were anti-HIV positive. It would be expected that the number

<sup>191</sup> CDR Review, no 8, 17 July 1992 [LIT.001.4789]

of additional cases of infection identified after October 1986 would be much lower, again because of testing. Sixty additional cases from 1022 males tested would reflect that, though it is not clear when they were infected and the true number of additional infections may be lower still.<sup>192</sup>

**10.159** However, it is not possible, on the basis of these figures, to express any confident view of the scale of the epidemic in England and Wales and therefore of the scale of the problem in the UK as whole. Only general impressions of the scale and development of the epidemic can be suggested.

**10.160** There is inevitably a lack of certainty about the end of the epidemic so far as NHS patients are concerned – in terms of the date when HIV was last transmitted to a blood disorder patient by replacement therapy or to a patient receiving blood or blood components in the course of medical or surgical procedures. Factor VIII concentrates issued from January 1985 were heat-treated to inactivate HIV and heat-treated Factor IX was routinely issued from October that year. Meantime, routine anti-HIV screening of blood donations had been introduced on 14 October 1985. It is not possible to exclude completely the possibility that there might have been transmission of HIV to NHS patients after these procedures were in place.<sup>193</sup> Human error might have occurred, resulting in the clinical use in or after January 1985 of Factor VIII that had not been heat-treated but had remained in stock. There is the same transitional risk with Factor IX around October 1985 and unscreened blood or components might have been used after 14 October 1985. However, it seems reasonable to take these three events as marking the end of the period of risk for most patients.

**10.161** The numbers of patients infected with HIV were not determined until later. Final numbers, so far as ascertained by the Inquiry, are discussed in Chapter 3, *Statistics*.

## Summary

- Throughout the period when HIV transmission was a significant threat to recipients of blood, blood components and blood products, data on the numbers of individuals infected were incomplete and generally underestimated the extent of the developing epidemic.
- Adoption of the CDC test for AIDS, the identification of intractable AIDS-defining disease, without a requirement to report significant evidence of impaired cell-mediated immunity, inevitably had an impact on the understanding of the developing epidemic until late 1984 when testing for anti-HTLV-III became available.
- As a result, government and NHS agencies did not have accurate information on the scale of the epidemic as a guide to policy generally and in particular as a guide to management of blood disorder patients.
- In retrospect it is clear that the voluntary reporting system did not secure comprehensive reporting of the numbers of patients infected.

<sup>192</sup> Since the earlier surveys were incomplete, it cannot be concluded that all of the 60 cases were new infections after October 1986: they may equally have been omitted from the earlier data because they were registered at Haemophilia Centres which refused to provide data.

<sup>193</sup> One case is noted in the Preliminary Report at paragraph 8.194

- Neither the UKHCDO nor any other professional group had authority to require disclosure of the anonymised data which were needed properly to measure the emerging pattern of infection in blood disorder patients.
- There were no rules of conduct prescribed by any government agency with responsibility for the administration of the National Health Service that required such disclosure.
- This is an area in which the apparently unquestionable independence and autonomy of the medical consultant seriously inhibited the collection and analysis of information essential to a full understanding of these emerging diseases and their implications for the patient population.
- As a result, the extent of the AIDS epidemic in recipients of blood, blood components and blood products in the UK generally has only become apparent following extensive retrospective analysis.

## CHAPTER 11

### HIV/AIDS AETIOLOGY

#### Introduction

**11.1** This chapter discusses the aetiology of AIDS: the cause or causes of the Acquired Immune Deficiency Syndrome that exposed individuals to disproportionate risk of opportunistic infection, cancers and other diseases of the AIDS complex, as disclosed in public debate, professional literature and the written and oral evidence provided to the Inquiry.

#### *Inter-disciplinary research in the 1980s*

**11.2** Medical and scientific understanding of the epidemiology of AIDS, as set out in Chapters 9 and 10, *Knowledge of the Geographic Spread and Prevalence of HIV/AIDS 1 & 2*, provided the context for discussion of the cause or causes of the disease as well as the modes of transmission of infection. It is necessary, however, to repeat a note of caution at the outset. Multi-disciplinary research and cooperation were less well-developed features of medical and scientific practice in the 1980s compared to contemporary practice. There was a lack of coordination of the research of groups working on similar problems but focusing on their own specialist interests. So, virologists and infectious diseases specialists might take one view of emerging evidence of disease while haematologists and haemophilia clinicians might take different views. Fractionators – those involved in the manufacture of blood products – responded quickly to the Barré-Sinoussi article in *Science* on 20 May 1983 (the seminal publication by the Montagnier group at the Institut Pasteur in Paris announcing the isolation of a putative AIDS-causing virus, discussed at paragraph 11.90, below).<sup>1</sup> Their approach was influenced by their apprehension that their products were already transmitting non-A, non-B Hepatitis. Professor Ian Hann, Director of the West of Scotland Paediatric Haemophilia Centre, Yorkhill, Glasgow, between 1983 and 1987, thought that one of the beneficial lessons of the HIV era was the need for multi-disciplinary teams,<sup>2</sup> but in the early 1980s that did not generally happen. As a consequence, what might have been known to one discipline about an emerging syndrome cannot be assumed to have been known to another and, in particular, what was published (still, at this stage, largely in paper form) in even a prestigious publication of specialist interest to one professional discipline cannot be assumed to have been read by specialists in other areas. The material years of the early 1980s were before the advent of electronic literature searches now considered routine.

**11.3** In modern practice, the degree of insularity that appears to have existed would be considered inappropriate. With the benefit of hindsight, practice in the 1980s might be the subject of adverse comment but it is difficult to re-create the medical environment without imposing on it changes in attitude and developments in practice that would only be achieved later, often in the light of experience with HIV/AIDS and the Hepatitis C virus. The reality is that one cannot assume homogeneous dissemination of information or a common understanding of that information among the disparate groups of scientists and clinicians who became interested in AIDS in the early 1980s. It is particularly important

---

<sup>1</sup> Barré-Sinoussi et al, 'Isolation of a T-Lymphotropic Retrovirus from a Patient at Risk for Acquired Immune Deficiency Syndrome (AIDS)', *Science*, 20 May 1983 [LIT.001.0058]

<sup>2</sup> Day 21, page 57

to bear in mind the possibility that a fact well known to and understood by an infectious diseases specialist, for example, might have been wholly unknown to, or if known misunderstood by, a haemophilia specialist, even though each might have had an interest in patients with the same or similar infections.

**11.4** Apart from differences among clinical specialists, there are likely to be differences between (i) the information and knowledge available to clinicians as a whole and (ii) the information and knowledge developed by scientists engaged in fundamental research, especially where there may be intellectual property rights to be protected. This chapter will leave the second topic for discussion in Chapter 29, *Discovery of HIV and Developments of Screening Tests*. Although scientific research overlapped in time with the events discussed in this chapter, and merged with them in 1984, progress in understanding of the aetiology of AIDS developed independently between the groups engaged in public debate and those pursuing confidential projects.

**11.5** These factors add further difficulty to what is inevitably a complex and difficult exercise: tracing changing theories of the cause of AIDS and assessing their relevance to scientific investigation and clinical practice.

**11.6** The controversies surrounding the possible cause of AIDS effectively ended by mid- to late 1984 with the confirmation that the lymphadenopathy-associated virus (LAV)/ human T-cell lymphotropic virus III (HTLV-III) was the pathogen responsible for transmitting infection. The developments in thinking up to that time are recounted at some length. Tragically, the majority of individuals infected with HIV – either those with bleeding disorders or following transfusion with infected blood – acquired the virus between early 1982 and mid-1984 when there was no settled understanding of the cause or causes of AIDS. There is natural, and wholly understandable, concern that in some way AIDS was ‘allowed’ to happen when it could, and should, have been controlled. If that concern is to be addressed, at the very least it is necessary to have information that is as reliable as possible about events as they unfolded.

### Early reports and first thoughts

**11.7** Early reports of the disease are discussed in the Preliminary Report and in Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV 1*. The initial debate on AIDS, as published in 1981 and 1982, was heavily influenced by the fact that most of those reports dealt exclusively with homosexual men.<sup>3</sup> An association with some aspect of a homosexual lifestyle or disease acquired through sexual contact was promoted as a cause of the disease. Cytomegalovirus (CMV) infection, sometimes associated with cellular-immune dysfunction, was prevalent among male homosexuals and there was speculation at the end of 1981 that there was a causal link. Michael Gottlieb and colleagues reported that four young previously healthy homosexual men, whose clinical manifestations were similar to the group originally reported in June 1981,<sup>4</sup> all had CMV infection and this was suggested as a major factor in the pathogenesis (causation and development) of the immunocompromised state.<sup>5</sup> Other possibilities canvassed included abnormal responses

<sup>3</sup> Evatt ‘The tragic history of AIDS in the hemophilia population 1982–1984’, *Journal of Thrombosis and Haemostasis*, 2006; 4/11:2295–2301, (reprint) [PEN.016.1183] at 1185

<sup>4</sup> See Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*, paragraph 9.18

<sup>5</sup> Gottlieb et al ‘Pneumocystis carinii pneumonia and mucosal candidiasis in previously healthy homosexual men’, *New England Journal of Medicine*, 1981; 1425–1431 [LIT.001.0779]

to Epstein Barr virus (EBV) or Hepatitis B virus.<sup>6</sup> It was thought that seminal fluid might be an important vehicle of CMV transmission. This suggested the possibility that common exposure predisposed male homosexuals to opportunistic infections.<sup>7</sup>

### *A genuinely new disease*

**11.8** AIDS seemed to be a genuinely new disease.<sup>8</sup> At the International Symposium on Infections in the Immunocompromised Host held in June 1982, a lecture on AIDS in homosexuals and drug addicts was 'the talk of the meeting'. Professor Hann said that after the lecture there was an atmosphere of extreme puzzlement. He explained:

[A]lthough we knew some viruses, like Epstein Barr virus, the glandular fever virus, other Herpes viruses like cytomegalovirus, could cause immune deficiencies, nothing remotely like this had ever happened before.

So we needed to prospectively study apparently normal gay people at that time, intravenous drug abusers et cetera, and see what it was that was making them immune deficient.<sup>9</sup>

**11.9** In relation to the cause of this syndrome, he said that the preferred belief among the experts present at the symposium was that it was most likely that a new viral agent or that several viruses might be involved.

**11.10** When the first cases were reported at the beginning of the 1980s, HTLV-III appeared to be a unique infection.<sup>10</sup> AIDS was considered to have no relevant history. It is now thought that HIV is a zoonosis – a pathogen transmitted from another species and in this case a descendant of a Simian Immunodeficiency Virus (SIV).<sup>11</sup> There are two types. HIV-1 is the more predominant, probably causing more than 98% of the human infections. It is believed that it was passed from chimpanzees to humans in West Africa in the early part of the twentieth century. HIV-2 has a different structure that is very closely related to a virus found in the sooty mangabey monkey species. Professor Andrew Lever, Professor of Infectious Diseases at Addenbrooke's Hospital, Cambridge, explained:

[T]he evidence is that HIV-2 crossed into humans from the sooty mangabey, whereas HIV-1 crossed into humans from the chimpanzee. Both of these, almost certainly – as I think it's well understood now – came into the human race, as far as we can tell, through the bush meat trade, where wild monkeys are caught and slaughtered and butchered and sold for food, and since both viruses are blood-borne and in fact in the monkey population they're transmitted predominantly by blood – by fighting, by biting and scratching – then it's relatively easy to think of how a virus may have been transmitted from fresh meat into someone who was handling that.<sup>12</sup>

<sup>6</sup> Professor Hann – Day 21, pages 43–44

<sup>8</sup> Dr Winter – Day 15, page 111

<sup>9</sup> Day 21, pages 43–44

<sup>10</sup> Professor Lever's Report [PEN.015.0517] at 0518

<sup>11</sup> Zoonosis, or 'spillover', is relatively frequent, with up to 60% of known human diseases estimated to be zoonotic in origin. SARS (Severe Acute Respiratory Syndrome) is another, more recent example. 'Viral chatter' – tracing the emerging 'incursions' of zoonotic diseases – is an important part of virological research.

<sup>12</sup> Day 26, page 27

**11.11** Once passed to humans, SIV mutated to become HIV.<sup>13</sup> Over time, HIV spread from Africa to the West and, in particular, to the USA.<sup>14</sup>

**11.12** In the early 1980s, comment focused on the novelty of the emerging features of the disease, such as *Pneumocystis carinii* pneumonia (PCP) or Kaposi's sarcoma (KS), in apparently healthy homosexual males who had not previously had clinically apparent immunodeficiency. There was also speculation that homosexual men contracted the disease because their immune system was not working properly, having been compromised by so-called 'recreational' drugs taken for stimulation.

### **Risk factors**

**11.13** By mid-1982, the mix of homosexual and heterosexual patients, intravenous drug abusers and haemophilia patients suggested that risk factors might be different for different groups. At this stage, in the first half of 1982, a blood-borne virus, spread by sexual relations, had been postulated but there was great uncertainty.<sup>15</sup> Other mechanisms were suggested, especially in the case of haemophilia patients, and it has become clear with the passage of time that some haemophilia patients did indeed develop different immune disorders, not dissimilar to those associated with HIV but without a viral agent of transmission of infection and with apparently different outcomes.<sup>16</sup>

**11.14** Professor Lever said that information about infection in drug users was an additional piece of the jigsaw:

Until that time there were plausible arguments that what was being seen, which was effectively confined to the gay, homosexual population, might have had a number of causes and ... people initially started looking for things they could find, which was why cytomegalovirus and Hepatitis B came up, and the fact that these populations were almost uniformly positive for these viruses, whereas the general population has a much lower incidence overall, made them potential candidates. But there was also an uncovering of information about the gay lifestyle at the time, about sexual promiscuity and about drug abuse, which also distinguished that population to some extent, certainly in the level of it, from most other populations. So there was room for a lot of speculation as to what might be triggering the immunodeficiency.<sup>17</sup>

**11.15** It was speculated that abnormal exposure to pathogens in the rectum and in the gut associated with male homosexual practices was significant. However, intravenous drug users, as a population, did not characteristically indulge in homosexual practices: heterosexual transmission affected the range of speculation related to homosexual behaviour and pointed to something that was probably common to both types of sexual conduct. As put by Professor Lever, it would have been logical to be looking for the common element: what was going wrong with the patients' immune systems.<sup>18</sup>

<sup>13</sup> (1) Gao et al, 'Origin of HIV-1 in the chimpanzee *pan troglodytes troglodytes*' *Nature*, 1999; 397:436 [LIT.001.1178]; (2) Bailes et al, 'Hybrid origin of SIV in chimpanzees', *Science*, 2003; 300:1713 [LIT.001.1184]; and (3) Wolfe et al, 'Naturally acquired simian retrovirus infections in Central Africa hunters', *The Lancet*, 2004; 363:932 [LIT.001.1185].

<sup>16</sup> See the discussion of the 'antigen overload theory' later in this chapter.

<sup>17</sup> Day 26, pages 32–33

<sup>18</sup> Day 26, pages 36–37

**11.16** Other heterogeneous theories were discussed and were explored by different specialist groups. One, relating to retroviruses, was to become important but in retrospect it appears to be clear that there was as yet, in the first half of 1982, a lack of cross-fertilisation of ideas among those taking an interest in this new phenomenon.

## **A widening constituency and the infective agent theory**

### *A widening constituency*

**11.17** Reports of opportunistic infections among Haitian immigrants to the USA and additional cases of PCP in haemophilia patients in July 1982, and of intravenous drug abuse as a risk factor in September 1982, marked a further material change in context away from an exclusive focus on sexual behaviour.<sup>19</sup> The initial hypothesis linking the condition only to sexual behaviour could not be sustained: it was no longer possible to focus exclusively on such behaviour and theories related exclusively to homosexual conduct and lifestyle were largely discarded.

**11.18** Three US haemophilia patients who reported with opportunistic infections in July 1982 had all received frequent administration of Factor VIII concentrate.<sup>20</sup> No two had received concentrate from the same batches. PCP had not previously been reported among haemophilia patients who had no other underlying disease and who had not had therapy associated with immunosuppression.<sup>21</sup> Possible transmission of an agent through blood products was suggested.

### *Dr Bruce Evatt and the infective agent theory*

**11.19** The report of these cases reflected the findings and views of Dr Bruce Evatt of the US Centers for Disease Control (CDC). The CDC had a supervisory function relating to off-licence use of certain drugs. At the material time, pentamidine, an antibiotic with certain conventional applications, was used for the treatment off-licence of PCP. Controlled issue allowed the CDC to build up a national epidemiological map of putative diagnoses of the disease, hitherto extremely rare and, where it did occur, almost always confined to immunosuppressed patients such as those undergoing chemotherapy.<sup>22</sup> In early 1982, Dr Evatt had received a report of PCP in a haemophilia patient and similar reports relating to Haitian patients, although previously haemophilia had not been among the underlying disorders of patients for whom pentamidine had been requested for PCP.<sup>23</sup> His organisation began surveillance of requests for pentamidine for haemophilia patients who were contracting PCP and several applications were received in quick succession in June and July.<sup>24</sup> It was inferred within the CDC that a new form of immune suppression was occurring in the haemophilia community.<sup>25</sup> Dr Evatt was convinced that AIDS had reached haemophilia patients.<sup>26</sup> Dr Mark Winter, who became Consultant Haematologist at Kent and Canterbury Hospital in 1983, said that Dr Evatt was the doctor who identified the haemophilia patients in 1982 with what became known as AIDS.<sup>27</sup>

<sup>19</sup> See Chapter 9, *Knowledge of the Geographic Spread and Prevalence of HIV/AIDS 1*, paragraphs 9.20–9.22

<sup>27</sup> Day 15, pages 112–113

**11.20** Dr Winter commented:

Prior to July 1982 the disorder was known as GRID, Gay Related Immuno-Deficiency, and it was these reports of July 1982 that really changed the favoured aetiological agent, obviously enough towards a virus. The fact that here were this small number of patients with a blood disorder, treated regularly with blood products, here were they with the same disorder, that made viral aetiology very much more likely than the previously favoured theories, and then obviously we only had to wait a few more months before there was much clearer evidence that it was likely to be a viral disorder even though the virus had not at that time been identified.<sup>28</sup>

**11.21** Not everyone was convinced and Dr Evatt's views were not generally accepted at the time. Opinion that the disease was likely to be due to a blood-borne transmissible agent hardened to some extent after July 1982 but unanimity was not achieved. There remained considerable divergence of views on the aetiology of the disease. Dr Evatt's views met with particular resistance among haemophilia clinicians.

**11.22** Specialists in infectious diseases also saw difficulties. Professor Lever told the Inquiry that, at that time, there were hints that this new illness might be an infection but that it did not have the usual characteristics of an infection. With chronic infections such as hepatitis, the immune system would be activated to try to clear the infection. One of the mysteries with AIDS was the apparent deterioration of the immune system: 'It was almost like a degenerative disease, things were failing, and there was no obvious evidence before testing came along that the body was doing anything about it.'<sup>29</sup>

**11.23** Professor Lever thought that individual physicians and the people at the CDC whose job it was to study the epidemiology would have been looking for a common element causing suppression of the immune system, taking into account the unusual infections and malignancies that were affecting different groups.<sup>30</sup>

**11.24** Epidemiological studies, begun shortly after the initial reports of the disease, confirmed that the constellation of symptoms seen in homosexual men was also seen in the additional groups found to be infected and in heterosexuals with multiple partners. The need for a more broadly-based hypothesis was reinforced by the report in December 1982 of four more cases of heterosexual haemophilia patients with opportunistic infections in the USA<sup>31</sup> and, in the same month, the report (by Dr Arthur Amman and others) of a possible transfusion-related case of AIDS in a 20-month-old child from San Francisco.<sup>32</sup> The child had been treated with an infusion of platelets from a donor who subsequently died of PCP. This case, and another of a child under 10 years of age, suggested that an association with sexual conduct was unlikely.

<sup>28</sup> Day 15, page 114. Similar views were later reported by Dr Margaret Ragni: 'AIDS and treatment of hemophilia patients', *Plasma Therapy and Transfusion Technology*, 1988; 9:173 [SGF.001.1314]

<sup>32</sup> 'CDC Possible transfusion-associated acquired immune deficiency syndrome [AIDS] – California', *MMWR*, 1982; 31:652–654 [SGH.008.5105] at 5108. Dr Amman and others reported the case in April 1983 in *The Lancet*: 'Possible Transmission by Means of Blood Products' [LIT.001.0405]

### *The 'San Francisco child' debate*

**11.25** There was, however, considerable divergence of opinion on the case of the infant from San Francisco. As noted in Chapter 9, *The Geographical Spread and Prevalence of HIV 1*, paragraph 9.32, the *Morbidity and Mortality Weekly Report (MMWR)* editorial of 10 December 1982 advised caution. Professor Christopher Ludlam, Director of the Edinburgh Haemophilia Centre during the reference period, commented that it was not a definite case of AIDS. He speculated that the child could have had a congenital immune deficiency, notwithstanding that there was an infected donor.<sup>33</sup> He agreed that it was a significant event, although not a 'clinching' one.<sup>34</sup> Professor Lever said that the case was 'compelling but not absolutely conclusive'. He also pointed out that the genetic background of the child was unknown, as was his particular susceptibility to illness which could have made him more prone to an infection. He thought that, taken with other knowledge at this time, it was 'more and more suggestive of an infectious agent and a transmission by blood products. But it doesn't close the door'.<sup>35</sup> Later, when discussing the differing hypotheses emerging around this time, Professor Lever returned to this case and commented that a very young child, months old, was not something to hang a whole case on because 'some two per cent of children are born with some oddity about them, some minor difference from the average'.<sup>36</sup>

**11.26** On the other hand, Dr Winter's view was that the report of infection in the San Francisco infant was a critical point in the developing history.<sup>37</sup> After that, it was no longer possible, in his view, to support the theory that the disease was related to the lifestyle of homosexuals rather than that it was caused by an infectious agent. He expressed his view strongly:

By December 1982 ... [a]ny clinician looking at this data would have to believe that AIDS was a transmissible disorder and that it could have been transmitted by blood and blood products. It was the only clinical interpretation of the data that was available.<sup>38</sup>

**11.27** On the evidence as a whole, however, Dr Winter was ahead of other opinion in arriving at this conclusion. It was inconsistent with Dr Peter Kernoff's reported views at the time and with the views of Professor Lever and Professor Ludlam, expressed in retrospect, among others. It is clear that a further major split in opinion was to develop, as Dr Winter indicated, but that was to come later.

### *Koch's postulates*

**11.28** At a workshop convened on 4 January 1983 in Atlanta there was a hostile reaction to Dr Evatt's argument.<sup>39</sup> As he reported it, there were calls to 'Show us the agent ... subject it to Koch's postulates'.<sup>40</sup> At the end of the workshop it was said that the biggest question of all remained what caused AIDS. In relation to the infective agent theory, Dr Louis Aledort, Director of the Haemophilia Center at New York and a respected US

<sup>39</sup> Research News: 'Health Officials Seek Ways to Halt AIDS' [LIT.001.1589]

<sup>40</sup> Evatt, 'The tragic history of AIDS in the hemophilia population 1982–1984' *Journal of Thrombosis and Haemostasis*, 2006; 4:2295–2301, (reprint) [PEN.016.1183] at 1188. For competing views, see Marx, 'Health Officials Seek Ways to Halt AIDS', *Research News*, 21 January 1983 [LIT.001.1589]

haematologist, was and remained for some time a prominent sceptic. He was one of a group of clinicians who found it particularly difficult to accept that blood products were transmitting an infectious agent.<sup>41</sup> Dr Aledort favoured the idea that haemophilia patients were exposed to a great number of foreign antigens in the course of treatment and experienced a high degree of antigenic stimulation that effectively wore out their immune systems: the 'antigen overload theory'.

**11.29** The resort to Koch's postulates by the CDC's opponents perhaps reflected the full extent of the divergence of opinion at the time. Robert Koch was a 19th-century German physician who set out criteria that he thought necessary to prove that an infectious agent (at the time typically bacteria) was the cause of a particular illness when transmitted from one person to another.<sup>42</sup> Professor Ludlam outlined the requirements:<sup>43</sup>

- The bacteria must be present in every case of the disease.
- The bacteria must be isolated from the host with the disease and grown in pure culture.
- The specific disease must be reproduced when a pure culture of the bacteria is inoculated into a healthy, susceptible host.
- The bacteria must be recoverable from the experimentally-infected host.

**11.30** If Koch's postulates were satisfied, that demonstrated to a satisfactory standard that a particular disease was caused by an infectious bacterial agent.<sup>44</sup> The postulates did not supply proof to the standard of a mathematical or scientific certainty, however, that the specific bacterial agent caused the specific disease. It remained a test of probability according to Dr Winter.<sup>45</sup> Consistent with Dr Winter's evidence, Professor Lever said that Koch's postulates were valuable as a guide but they were not the final definition of whether something was an infection. He also explained that the postulates were much more difficult to apply to viruses:

[B]ecause viruses only grow within living cells and if one doesn't have the appropriate cells in culture in which that virus can grow, or one cannot keep the appropriate cells alive, one cannot fulfil the second of Koch's original postulates.<sup>46</sup>

**11.31** In early 1983 the agent of transmission, HIV, had not been identified. It could not be known that, if there were an agent of transmission, it would necessarily share common characteristics with bacteria that would enable the postulates to be satisfied. Furthermore, AIDS was not a 'specific' disease. The disease manifestations of AIDS included PCP and KS but the full spectrum ranged from cases of proven cell-mediated immune deficiency without symptoms to non-specific symptoms associated with laboratory evidence of immune deficiency. The CDC definition for reporting purposes by this stage identified AIDS as a disease, at least moderately predictive of a defect in cell-mediated immunity, occurring in a person with no known cause for diminished resistance to that disease. Koch's postulates would have required adaptation for application to the identification of an infective agent for the transmission of AIDS.

<sup>41</sup> Professor Ludlam – Day 18, page 115

<sup>42</sup> Dr Winter – Day 16, page 5. (Koch is widely regarded as the founder of modern bacteriology and discovered the aetiological agents of anthrax, cholera and tuberculosis.)

<sup>43</sup> Day 19, pages 8–9

<sup>44</sup> Professor Lever – Day 26, pages 57–58

<sup>45</sup> Dr Winter – Day 16, page 6

<sup>46</sup> Day 26, page 55

**11.32** There are other reasons for concern that Koch's postulates may have been relied upon. Fully developed AIDS, as understood from the earliest stages of the epidemic, was associated with high mortality. Leaving aside the first two postulates, the infusion of blood from a known AIDS patient into a susceptible, healthy host – another human being – with an inherent risk of causing potentially fatal disease could not have been justified. By the time it was accepted that HIV was probably the agent of transmission, so that the first two postulates might have been tested, the risk of incurable and potentially fatal disease was so well established that it would have been unthinkable to expose a healthy, susceptible human host to infection to test the postulates.

**11.33** So far as the UK is concerned, Professor Ludlam stated that he had no recollection of Koch's postulates featuring in the discussion around this time (in 1983). He emphasised that in clinical medicine one worked the whole time with incomplete data and information, making assumptions that may not be backed up by scientific evidence.<sup>47</sup> In relation to the infant who had received a transfusion of platelets (reported in the *MMWR* of 10 December), Dr Winter thought that 'because you had ... three parts of the equation – the donor, the recipient and the blood transfusion – it could have been said to have fulfilled Koch's postulates.'<sup>48</sup> Professor Lever said that some clinicians took the approach that if most of the postulates were satisfied, it was more likely than not an infectious agent but that other clinicians did not agree with this approach.<sup>49</sup> Controversy reigned.

**11.34** By the end of 1982 and in to 1983 the aetiology of AIDS remained, technically, unknown so far as Koch's postulates were concerned: the full requirements of the postulates had not been fulfilled.<sup>50</sup> At the Atlanta conference the opponents of Dr Evatt's views regarded his evidence as anecdotal in the absence of proof to that standard. The CDC was dismayed by the outcome of the Atlanta conference.<sup>51</sup>

**11.35** Koch's postulates were an impossible test at the time. The demand for proof to that standard demonstrates the resistance among highly respected US clinicians to the infectious agent theory but leaves open the question whether that resistance was based on scientific grounds or reflected wider concerns about the implications for haemophilia therapy if the theory was given credibility.

### *Altered immunological states in haemophilia patients*

**11.36** On 29 January 1983, Dr Margaret Ragni and others reported altered immunological states in two multiply-transfused patients with severe haemophilia.<sup>52</sup> They commented:

The lymphadenopathy and immunological features in these two haemophiliacs bear a striking resemblance to the acquired immunodeficiency syndrome (AIDS) of homosexuals, intravenous drug abusers, and Haitian immigrants. These findings may represent a prodromal [early, often asymptomatic] phase or forme fruste [atypical manifestation] of AIDS. Transmission of an infectious agent in blood products seems likely.<sup>53</sup>

<sup>52</sup> Ragni et al, 'Acquired immunodeficiency-like syndrome in two haemophiliacs', *The Lancet*, 29 January 1983, 213 [SNB.007.3455]. See also Dr Ragni's comments in 'AIDS and Treatment of Hemophilia Patients', *Plasma Therapy and Transfusion Technology*, 1988; 9:173 [LIT.001.0598]

<sup>53</sup> Ragni et al, 'Acquired immunodeficiency-like syndrome in two haemophiliacs', *The Lancet*, 29 January 1983, 213 [SNB.007.3455]

**11.37** Professor Ludlam commented that at this time it was unclear whether individuals with the features reported by Dr Ragni and her colleagues were likely to get AIDS but that the study provided further evidence for AIDS in haemophilia patients being caused by an agent transmissible in Factor VIII concentrate.<sup>54</sup>

**11.38** By the summer of 1983 there was continuing doubt in some segments of the haemophilia community, in the blood banking industry, and among physicians and the Food and Drug Administration (FDA) in the USA that AIDS was a blood-borne infection.<sup>55</sup> There was no consensus that the disease was transmitted by a virus and, until Robert Gallo's announcement in 1984, no generally accepted evidence of a candidate for transmission.<sup>56</sup>

**11.39** There were similarly differing views in the UK. Dr Winter was asked whether there was particular resistance to the transmissible agent theory, on the part of at least some haemophilia clinicians in the UK, because of the advantages of using concentrates. He said:

I think ... that was the case. The initial – if you like, the clinicians didn't want to believe any of this data, because we [had] just been through such a very major advancement in healthcare. So that would have been the mindset originally and then they are looking at this American data and the next thing is, okay, these patients – they are a very small number and there were no British ones and there were no German ones, so I'm just going to keep on looking at the situation, and now you have a situation, December 1982/January 1983, I can't ignore this any more. These patients must have a disorder that's caused by blood transfusion in the forms of the concentrates. So maybe in Britain things will be fine if we now just switch or do all we can to use British concentrate.

In America it was the same ... the clinicians didn't want to believe it, the commercial companies didn't want to believe it, the blood transfusion services didn't want to believe it because they were particularly sensitive about excluding certain risk groups as donors. There were lots of political issues around that. So none of the related agencies wanted to know this. That's why, if you like, I'm sure, this data took some time to really hit home.<sup>57</sup>

**11.40** He continued:

So deeply engrained in the psyche of haemophilia clinicians, as in the patients ... was the concept that British blood was likely to be much freer from viruses than American blood. So here we were in 1982, we already knew about hepatitis, we already knew about the increased risk from commercial donors. Here was now what looked like a transmissible disease that also appeared to be occurring in these same unsavoury American blood donors. This reaffirmed the view that these things weren't likely to happen in British blood donors.<sup>58</sup>

<sup>54</sup> Historical Summary of AIDS in Haemophilia 1981–1985 [PEN.015.0468] at 0468–9

<sup>55</sup> Evatt, 'The tragic history of AIDS in the hemophilia population 1982–1984', *Journal of Thrombosis and Haemostasis*, 2006; 4:2295–2301 (reprint) [PEN.016.1183] at 1189

<sup>56</sup> It is interesting to compare the development of thought in relation to hepatitis. See Chapter 15, *Knowledge of Viral Hepatitis 2, 1975 to 1985* paragraph 15.24. Alter et al applied the postulates, only to set them aside as research proceeded and the realities of the disease required a more flexible approach.

<sup>57</sup> Day 16, pages 28–29

<sup>58</sup> Day 16, pages 29–30

**11.41** On the evidence now available to the Inquiry there was, on one view, ample circumstantial evidence by early 1983 of an association between some blood products and transmission of infection. Infected patients had received large amounts of concentrate; none had prior opportunistic infections; their personal and environmental histories were different; and two were 10 years of age or less. It would have been open to infer that the whole group of infected patients would not fall within any of the other known at-risk categories of promiscuous homosexuals, heroin addicts and immigrants into the USA from Haiti. However, the proponents of the several theories were divided on a more basic level reflecting interests that were not wholly scientific in origin. The resistance of the haemophilia clinicians appears to have reflected their wish to continue to use factor concentrates of proven efficacy in treating their patients. The pharmaceutical industry had commercial interests to protect. Human nature rather than the strict application of scientific theory probably contributed to the persisting differences of opinion.

### Competing theories in 1983

**11.42** While a common cause was postulated in the haemophilia population and in homosexual and other groups by some commentators, there were unresolved issues. In particular, once it was established that AIDS was occurring in the haemophilia population as well as in other risk groups, there was an apparently inexplicable difference in the pattern of disease. The haemophilia patients did not develop KS, whereas this was common in homosexual AIDS patients. The difference in the pattern of disease presentation probably contributed to the belief that there were different aetiological agents behind the diseases in the two groups.<sup>59</sup>

**11.43** It is now reasonably clear that there are likely explanations for the difference. Professor Lever told the Inquiry that it is now thought there are two or three possible explanations for the absence of KS in haemophilia patients with HIV infection. One is that HHV8 (otherwise KSHV, the herpes virus responsible for KS) may be very poorly transmitted by blood-borne routes. Transmission does occur by these routes, but it is certainly less easily transmitted than HIV. The amount of HHV8 virus present in the blood may be far less than the many millions of copies of HIV that one finds. Second, it may be far more easily transmitted by the sexual route and that would also be plausible because other herpes viruses are transmitted by mucus membrane contact. Classically, herpes simplex type 1, which causes the cold sore, is transmitted mouth to mouth or by saliva. EBV, another herpes virus, causes glandular fever and is sometimes known as 'the kissing disease'. So it is quite likely that sexual transmission of HHV8 is far more efficient than any other route. The third possibility is that a preparation technique might have been effective to inactivate in blood products what is a large and also relatively fragile, complex virus. Or the explanation might be a combination of the above.<sup>60</sup> These possible explanations of the differences in disease profile were, however, quite unknown in the 1980s.

**11.44** There were other uncertainties at that time. Professor Lever told the Inquiry that there were many people who from the beginning thought there was an infectious cause and many who did not. He thought that the issue was that there was no physiological appearance of an infection. He continued:

<sup>59</sup> Professor Lever's Report [PEN.015.0517] at 0520. HHV8/KSHV, the cause of Kaposi's sarcoma, was finally identified in 1994.

<sup>60</sup> Professor Lever – Day 26, page 76

The fact that you get a rash with measles is probably only there to tell the rest of the population that you are infectious and should be kept away from. The fact that you get a very high fever in some diseases doesn't actually do you very much good but it tells other people that you are ill. That's how mothers know their babies are ill because they feel hot.<sup>61</sup>

**11.45** The geographical spread was also unusual, although not unprecedented. Professor Lever advised that some infections could spread very rapidly but in this case there was no continuity or explosion of a cluster in one particular area.<sup>62</sup> In the period 1982–83 these and other uncertainties led to a more broadly-based study by virologists of immune deficiencies in cases of AIDS infection.

### *Haemophilia research*

**11.46** The publication of cases of AIDS in haemophilia patients, first in June and then November 1982, had prompted several groups of researchers in the USA to carry out immune studies in groups of asymptomatic haemophilia patients. It was known that the absolute number of certain cells ('helper' cells known as  $T_4$  or CD4 cells) and the ratio of those cells to another group ('suppressor' cells known as  $T_8$  or CD8 cells) provided a measure of cell-mediated immunity, the effectiveness of the immune system. The researchers found widespread depression of  $T_4/T_8$  ratios in their subjects and also found that depressed  $T_4$  counts were very closely related to exposure to US commercial Factor VIII concentrates. The 'immune overload', or 'antigen overload', theory developed as an alternative to a transmissible agent theory as an explanation of these immune disorders: the fact that immune abnormalities occurred in asymptomatic haemophilia patients receiving single or multiple-donor products suggested that immunological defects might arise from blood product treatment alone.<sup>63</sup> It was also relevant to the view developed at the time that there was uncertainty about what did constitute AIDS.<sup>64</sup>

**11.47** The major pathological feature of AIDS was very profound immunosuppression, with characteristic suppression of  $T_4/T_8$  ratios and hyperglobulaemia (an excess of globulin in the blood). Researchers began to explore ideas based on the hypothesis that there was a relationship between these immune phenomena and the aetiology of AIDS. During 1982 and into 1983 immune studies of homosexual men with no symptoms of AIDS showed similar, if less marked, immune phenomena (notably suppressed  $T_4/T_8$  ratios) to those with overt diseases characteristic of AIDS.

**11.48** On 13 January 1983, the *New England Journal of Medicine (NEJM)* published an article by Michael Lederman and others entitled 'Impaired cell-mediated immunity in patients with classic hemophilia'.<sup>65</sup> They studied 19 patients and 19 controls and, within the haemophilia group, distinguished those who had received Factor VIII concentrates from those who had received only cryoprecipitate.<sup>66</sup> The  $T_4/T_8$  ratio results for the latter group did not differ from the controls. The results for the group who had received Factor

<sup>65</sup> Lederman et al, 'Impaired cell-mediated immunity in patients with classic hemophilia', *New England Journal of Medicine*, 1983; 308/2:79–83 [PEN.012.0263]

<sup>66</sup> That is, in this case, 19 age-matched, apparently healthy people without haemophilia.

VIII concentrates were similar to those reported among populations of apparently healthy homosexual men. The authors thought that genetic haemophilia factors were unlikely to explain their findings. They stated:

A more likely possibility is that the immune dysfunction is acquired. Active infection with hepatitis B virus is probably not responsible, since none of the 11 patients in the group [treated with concentrates] had demonstrable hepatitis B surface antigenemia. The cause of the immuno-suppression in this population is not known ....<sup>67</sup>

**11.49** They commented that, among AIDS patients, epidemiological evidence would implicate a blood-borne pathogen as the cause of immunosuppression but offered no view as to whether this explained their findings.

**11.50** In the same issue of the *NEJM*, Jay Menitove and others also published immunology studies on apparently healthy haemophilia patients, differentiating those treated with cryoprecipitate obtained from volunteer blood donors and those treated with commercially prepared Factor VIII concentrates and further distinguishing groups according to dosage.<sup>68</sup> They set out to test the hypothesis that AIDS might be transmitted through Factor VIII infusion. They found that none of the cryoprecipitate users had abnormal  $T_4/T_8$  ratios while 57% of the users of commercial concentrates did have abnormal ratios. They noted that there had been speculation that AIDS might be transmitted to haemophilia patients through Factor VIII infusion. The article noted that the epidemiology of AIDS was suggestive of a blood-borne transmissible agent but it was not yet clear whether the abnormalities in cell-mediated immunity in patients with haemophilia and, in particular, in those who had also developed opportunistic infections were due to the putative blood-borne pathogen. The authors advised caution in the interpretation of the findings. They noted that the proposed explanations for AIDS included CMV infection, inhaled nitrates and exposure to foreign antigens, such as spermatozoa, and concluded:

Our data are consistent with the possibility that commercially prepared lyophilized factor VIII concentrates can induce an AIDS-like picture, but a large number of patients must be studied before a definite conclusion can be drawn. In addition, we cannot hypothesize about the emergence of this apparently new syndrome at this time. Whether the abnormalities found in our patients will evolve into clinical disorders remains to be determined, but we urge those involved in the care of patients who use factor VIII concentrate to follow them carefully for stigmata of AIDS and changes in immunologic status.<sup>69</sup>

**11.51** The opinions in these two articles in January 1983 were carefully qualified. Neither paper used the term 'immune overload' or any of the alternative expressions carrying the same meaning. However, to a greater or lesser extent each explored the underlying idea while not excluding a largely infective blood-borne cause of AIDS in haemophilia patients.

<sup>67</sup> Lederman et al, 'Impaired cell-mediated immunity in patients with classic hemophilia', *New England Journal of Medicine*, 1983; 308/2:79-83 [PEN.012.0263] at 0266

<sup>68</sup> Menitove et al, 'T-lymphocyte subpopulations in patients with classic haemophilia treated with cryoprecipitate and lyophilized concentrates' *New England Journal of Medicine*, 1983; 308:83-86 [LIT.001.0031]

<sup>69</sup> *Ibid* [LIT.001.0031] at 0033. They did not comment on the lack of fit between volunteer donors and commercial donor populations.

### *The 'immune overload' hypothesis*

**11.52** The hypothesis was that immune cellular dysfunction might be brought on by an 'overload' of normal immune responses, either by repeat introduction of foreign proteins contained in sperm or the repeated infusions of concentrates, or repeat infections with organisms such as CMV or EBV, leading to a state of immune suppression and presumably 'priming' the individual for an infection or other event leading to overt AIDS disease. Until early 1984, this theory gained support and, until the publication by Gallo of his identification of HTLV-III, was favoured by haemophilia specialists, some virologists and some immunologists.

**11.53** In an editorial in the same issue of the *NEJM*, Dr Jane Desforges commented that it was not yet known whether AIDS was secondary to multiple antigenic exposures, to a specific transmitted agent or to some other mechanism. The options were open.<sup>70</sup>

### *Antigen overload or a transmissible agent?*

**11.54** As indicated at paragraph 11.28 above, at the Atlanta meeting on 4 January 1983, Dr Evatt and his colleague, Dr James Curran, reported the findings and views of the CDC linking AIDS to a transmissible agent in blood products and noting that the risk for non-haemophiliacs was unknown but apparently small. The alternative theory was laid out. The hypothesis underlying Dr Aledort's theory was that prolonged exposure to foreign proteins had an impact on the immune system similar to that found in homosexual men and that AIDS was an end-stage development of these abnormalities.

**11.55** Both theories received media attention. There was comment on the issue in *The Observer* of 16 January 1983 in an article entitled 'Mystery Disease Threat'. The article commented on the infective agent theory. On the alternative point of view, the article quoted Dr Peter Kernoff from the Royal Free Hospital in London as saying:

"Assessing the risk is not a straightforward matter: we need much more hard evidence .... Factor VIII is a very valuable product and the advantages far outweigh the disadvantages."<sup>71</sup>

**11.56** Dr Winter thought that Dr Kernoff's comment reflected the position at the time:

He is a very respected figure looking at the data saying it is of concern, but we are talking about a product that has revolutionised the lives of patients and there is a major obvious benefit to this treatment. We will have to look at the risk that appears to be evolving. That was the situation of the day.<sup>72</sup>

**11.57** In the Department of Health and Social Security (DHSS), someone (name redacted) expressed the official view that:

[T]he value to severe haemophiliacs of clotting [Factors VIII and IX] far outweigh the possible and as yet unproven hazards of the transmission of acquired immune deficiency syndrome.<sup>73</sup>

<sup>70</sup> Desforges, 'Aids and Preventive Treatment in Haemophilia', *New England Journal of Medicine*, 1983; 308/2 [LIT.001.0040]

<sup>71</sup> 'Mystery Disease Threat', *The Observer*, 16.01.83 [DHF.001.7108]

<sup>72</sup> Day 16, pages 13–14

<sup>73</sup> Memo dated 18 January 1983: 'Factor 8 and the Observer Article' [DHF.001.7111]

**11.58** At the 19th Congress of the International Society of Haematology and 17th Congress of the International Society of Blood Transfusion in Budapest in August 1982, Dr Aledort discussed his experience with the cases of three haemophilia patients in the USA who had died from pulmonary infections characteristic of AIDS (as reported in the July *MMWR* – see paragraph 11.18 above). The theory was taken up by some haemophilia clinicians in the UK. On 15 January 1983, simultaneously with the two *NEJM* papers mentioned above, there was a report in *The Lancet* of altered immunology in English haemophilia patients.<sup>74</sup> The article, by Dr Peter Jones and others, Newcastle upon Tyne, noted that transfusion was immunosuppressive, in an as yet unidentified way, in renal transplantation and commented that an immunosuppressive syndrome associated with T-cell subset reversal had been noted in a small population of multiply-transfused, heterosexual haemophilia patients in New York. They commented on their own findings:

The alterations in T cell subsets in our survey may simply reflect temporary altered immune status in multitransfused individuals. But half our patients without T cell ratio reversal had been exposed to equally large quantities of blood. It could be that T cell ratio reversal is a normal defence mechanism to antigenic load, and that the patients without reversal show an abnormal lack of response.

None of our patients, who have all been exposed to commercial blood products of American origin, shows features of AIDS ....<sup>75</sup>

**11.59** The article by Dr Jones followed in date, but must have been submitted before, the workshop convened by the CDC in Atlanta on 4 January 1983.<sup>76</sup> At the date of its preparation, the antigen overload theory had a certain currency among other haemophilia clinicians in the UK. Professor Ludlam commented that this report of low  $T_4$  counts and  $T_4/T_8$  ratios suggested that the changes might be a response to antigenic load.<sup>77</sup> In his case, this initiated a research interest that came to have considerable importance for a time. Commenting later on a draft paper prepared for litigation in England and Wales 20 years ago,<sup>78</sup> he said:

[It was] possible that AIDS was arising in haemophiliacs because during the 1970s there was increasing use, massive increasing use of Factor VIII concentrates.

I mean, I calculated that at least using SNBTS concentrates, that in an average lifespan, you gave out a kilogramme of protein intravenously in an average severe haemophiliac. We are not designed to accept proteins in that magnitude intravenously. So one possibility was that actually – as we hinted earlier – maybe haemophilia as a whole was sliding into AIDS because of all the concentrate we were using. Quite separate from HIV or a putative virus.<sup>79</sup>

<sup>79</sup> Professor Ludlam – Day 18, page 150

**11.60** In March 1983, Jonathan Goldsmith and others wrote an article published in *The Annals of Internal Medicine* in which they considered the similarities in T-helper/T-suppressor cell ratios in haemophilia patients and in homosexual men, Haitian refugees and narcotics addicts.<sup>80</sup> They noted that a characteristic feature of the altered cellular immune functions in homosexual men was reduced  $T_4/T_8$  ratios and that it had been suggested that these abnormalities were the result of continued exposure to sexually transmitted viral infections, particularly CMV infection. They studied 12 apparently healthy haemophilia patients to ascertain if they had similar abnormalities in their lymphocyte sub-populations. The similarities in biometric abnormalities were striking in 9 of the 12 patients studied. However, none of the haemophilia patients had been exposed to nitrates and all had stable antibody titres to CMV.

**11.61** The conclusion relating to the haemophilia patients was that:

The presence of an abnormal ratio of helper to suppressor T-cells in these patients is of uncertain significance, and this observation needs to be confirmed .... In addition, since the establishment of the ... Regional Haemophilia Centre ... in 1976, no cases of pneumonia or chronic infection have occurred in our patients .... Whether patients with these T-cell defects are at increased risk for development of malignancy has yet to be substantiated. Reports from the literature, however, suggest that patients with congenital bleeding disorders have a prevalence of malignant disease similar to the general population. At this time there is insufficient evidence to advocate a change in therapeutic practices in these patients. However, additional patients with hemophilia need to be evaluated to ascertain if the magnitude of exposure to clotting factor concentrates is associated with an increased incidence of malignancy or opportunistic infections.<sup>81</sup>

**11.62** In early 1983 the antigen overload theory was supported by haemophilia clinicians on both sides of the Atlantic. Professor Lever explained that it was a compelling theory at that stage.<sup>82</sup> He suggested that the theory had probably originated in New York amongst the physicians looking after patients with HIV and amongst the gay population in New York itself. He thought that 'a physician in New York' (a description that Dr Aledort would have fitted) had put the antigen overload theory forward as an alternative, less stigmatising theory. With the benefit of hindsight, it could be speculated that they felt that if it was perceived that there was an infectious cause the gay population might be more stigmatised for transmitting agents which caused disease. The stigma was very real. Professor Lever described the scenes that occurred during the first Canadian conference on AIDS held in Montreal in May 1985.<sup>83</sup> The stage was taken by different pressure groups protesting about what had been seen to be media perceptions or medical professional perceptions. The prostitute population complained that being referred to as 'vectors of disease' was very demeaning. In South Africa it was deemed to be politically better for there not to have been a virus originating in Africa which caused the infection. These reactions would have established themselves in the minds of people who had vested interests in there not being a virus.

<sup>80</sup> Goldsmith et al., 'T-lymphocyte subpopulation abnormalities in apparently healthy patients with hemophilia', *The Annals of Internal Medicine*, March 1983 [LIT.001.0055]

<sup>81</sup> Ibid [LIT.001.0055] at 0057

<sup>82</sup> Day 27, pages 29–30

<sup>83</sup> The Conference was held with a view to bringing together the ideas and proposals for strategy held by affected groups. It led to the formation of the Canadian AIDS Society in July 1986.

**11.63** Professor Lever was anxious, however, to put the issue in context. As already noted, he emphasised that the initial manifestations of HIV did not look like a normal infection. They looked like something that was leading to degeneration or deterioration in the immune system. There had not been another infection which clearly did that. That was why theories of protein overload and theories of abuse of specific drugs like amyl nitrate were brought up. The disease could have been a toxic effect in the immune system. All of the theories were as plausible as each other. None of them had a majority view at the very beginning. Professor Oliver James, Medical Assessor to the Inquiry, had a similar impression of the early development of these theories.<sup>84</sup>

**11.64** The antigen overload theory persisted in parallel with the transmissible agent theory and remained competitively tenable until the virus was isolated.<sup>85</sup> Various agents were considered as possible causes of the new disease.

### *Scottish research*

**11.65** In Scotland, interest in the topic developed in Edinburgh and in Glasgow. In the context of haemophilia therapy, Professor Ludlam began a series of tests, described by him as 'screening' tests, in about the beginning of 1983.<sup>86</sup> His studies started after the first three cases of AIDS in haemophilia patients had been reported in the USA in July 1982 and followed the course of research into clinical immune deficiencies in homosexual men with AIDS. As already noted, a characteristic feature of these immune deficiencies was a reduction in blood CD4 lymphocyte numbers and a decrease in CD4/CD8 ratios. Similar decreases in CD4 numbers and CD4/CD8 ratios were found in intravenous drug users. Professor Ludlam explained that it was uncertain whether these were due to viral infection, chronic antigen stimulation or another aetiological factor. This stimulated his research into the position in asymptomatic haemophilia patients.<sup>87</sup>

**11.66** Professor Ludlam studied a large number of patients and found a pattern of suppression that seemed to have at least some parallels with the New York studies. Professor Lever explained that in the absence of an illness that looked like conventional infection one would look around for competing theories.<sup>88</sup> To ensure control of the tests, Professor Ludlam had the forms for samples labelled 'AIDS study'.<sup>89</sup> This was later to give rise to suspicion on the part of some patients that he was carrying out experiments on his patients. In the view of this Inquiry that suspicion was without foundation. Professor Ludlam explained that by the spring of 1983, it was becoming clearer that strange things were happening to the immune systems of patients with haemophilia who were otherwise feeling well.<sup>90</sup> He explained what he was doing:

In 1982/83 in the absence of any patient with an AIDS-defining illness, the only way to potentially investigate individuals to assess their possible susceptibility to developing AIDS was to assess their immune function by laboratory testing. By 1983 it therefore seemed important, as it did to many other haemophilia physicians, to investigate the immune status of patients under my care....

<sup>89</sup> Day 35, page 19

<sup>90</sup> Ibid, page 21

I was surprised to observe that many patients had immune abnormalities very similar to those reported from homosexual men and haemophiliacs residing in North America.<sup>91</sup>

**11.67** He said in oral evidence:

It was – the interpretation that you could put upon those was puzzling us. I would say that similar abnormalities were shown in gay men who were otherwise feeling well. And the question is in fact: were all these patients or all these individuals in the United States actually already infected with a latent, if you like, AIDS virus?<sup>92</sup>

**11.68** While his patients had immune abnormalities similar to those reported in homosexual and other populations in the USA, it was inferred that they could not have been infected with an AIDS virus and that, at least in Edinburgh, patients' immune disturbances were due to a non-AIDS-causing agent.<sup>93</sup> This raised the possibility that haemophilia patients in the USA and elsewhere might not be infected with an AIDS virus.<sup>94</sup> In the event, his oral evidence was that there were three groups: those with abnormal immune systems who were subsequently shown to be infected with HIV; those with abnormal immune systems who were not infected with HIV; and those with normal immune systems who were infected but in whom changes in the immune system had not yet begun.<sup>95</sup>

**11.69** A letter to *The Lancet* of 30 April 1983 by Robert Gordon of the US National Institutes of Health (NIH) put the antigen overload theory in a way that provoked a response from Professor Ludlam. Having noted that observations of altered distribution of T-lymphocyte sub-populations in haemophilia patients with AIDS was consistent with the hypothesis that the disease was caused by a transmissible agent, presumably a virus, in blood products, Dr Gordon continued by saying that the observations were:

[A]lso compatible, however, with the possibility that repeated administration of factor VIII concentrate from many varied donors induces a mild disorder of immune regulation by purely immunochemical means, without the intervention of an infection.<sup>96</sup>

**11.70** A response from Professor Ludlam and others appeared in *The Lancet* of 28 May 1983. It referred to Dr Gordon's letter and to the ongoing study of haemophilia patients in south east Scotland. By this stage in Dr Ludlam's continuing research programme, 23 patients who had received exclusively SNBTS Factor VIII in the past five years, most of whom had never received commercial concentrate, had been studied. In the majority of these patients, the  $T_4/T_8$  ratios were reduced. The letter stated:

Since there are no known cases of AIDS in our blood donor population it seems likely that the immunosuppression observed in haemophiliacs, as reflected by reduced T lymphocyte helper/suppressor ratios, results from infusion of foreign

<sup>91</sup> Professor Ludlam's Statement [PEN.015.0445] at 0448

<sup>93</sup> Day 19, pages 18 and 21

<sup>94</sup> Day 19, pages 16–18

<sup>95</sup> Day 19, pages 18–20. It was later found, in 1985, that those who were infected with HIV had the same abnormal T lymphocyte subsets after as they had had before transfusion of material infected with the virus, confirming to the satisfaction of Professor Ludlam and his colleagues that the abnormal T lymphocyte subsets were a result of the intravenous infusion of Factor VIII concentrates per se and not HIV infection: Ludlam et al, 'human T-lymphotropic virus type III (HTLV-III) infection in seronegative haemophiliacs after transfusion of Factor VIII', *The Lancet*, 3 August 1985 [SNB.008.3434] at 3436

<sup>96</sup> Gordon, 'Factor VIII products and disordered immune regulation' *The Lancet*, April 30 [LIT.001.0911]

protein or a ubiquitous virus rather than a specific AIDS virus in factor VIII concentrates.<sup>97</sup>

**11.71** Professor Ludlam's letter to *The Lancet* was published at or about the time that the results of Montagnier's work were coming into circulation.

**11.72** The course of study of immune abnormalities amongst haemophilia patients involved a number of projects and teams and continued into 1984 with many published papers, including Professor Ludlam's own work. The work demonstrated a range of immune disturbances similar to those observed in other risk groups: a reduction in CD4 counts, disturbed CD4/CD8 ratios and other immune abnormalities. In a summary of the position as he saw it at about this time, Professor Ludlam observed that there were several candidate viruses in the field, some known and some unknown or mutations of known viruses. In the case of homosexual men, 'antigen overload' from semen in the rectum and 'recreational drugs', such as amyl nitrate and isobutyl nitrate, were candidates. Proteins other than Factor VIII/IX in clotting factor concentrates used to treat haemophilia were another.<sup>98</sup> On his approach, it was inappropriate in mid to late 1983 to make an assumption that the AIDS in people with haemophilia was of similar aetiology to the AIDS in the other groups. It was known that, clinically, the spectrum of AIDS-related conditions differed to some extent as between the groups and so clinicians considered the possibility that they had arisen simultaneously, or nearly simultaneously, but were of different aetiologies.<sup>99</sup>

**11.73** At the Glasgow Royal Infirmary (GRI), Professor Charles Forbes was interested in the same phenomenon. His group's research on immune disorders was published in October 1983.<sup>100</sup> He said:

It was quite apparent that there was an association between the administration of large amounts of Factor VIII concentrate and the immune process, which was suppressed in many patients. A variety of other investigators were finding the same kind of abnormalities using a range of biochemical tests and the real question was what did this mean? Was there something in the Factor VIII or IX concentrates that did suppress these tests of immunity?<sup>101</sup>

**11.74** He explained:

We became interested because of the ability to measure so many of the factors in blood. And we were kind of thrown off the scent at this time by finding that a lot of our patients who had been highly treated, a lot of protein given to them, had abnormalities of various kind[s], not all the same kind, and we thought that it must be that their immune system was being suppressed by something in the plasma that they were given, and that was a view we took and explored for several years. And I think it was probably accurate to say that there were abnormalities but what they meant, we didn't know, and of course, some of it probably was that they were infected with the unknown virus, HIV. So we were looking for something but we didn't know what we were looking for at the time.<sup>102</sup>

<sup>102</sup> Day 17, pages 89–90

**11.75** So far as he was concerned, the mystery has not been resolved even now.<sup>103</sup> His evidence about the state of knowledge in the early 1980s was not clear.<sup>104</sup> He thought, however, that there was a lot of doubt and argument at the time: knowledge was not hard and fast.<sup>105</sup>

***The infective agent theory***

**11.76** As noted in paragraph 11.55, an article was published in *The Observer* in January 1983 commenting on the competing theories. In relation to the infective agent theory, it stated:

A commercial blood product imported into Britain from the United States, may pose a grave threat to the health of haemophiliacs who inject it to encourage clotting ....

[I]t is being linked in America with a devastating and mystifying disease previously associated with homosexuals, which causes a serious breakdown in the body's immunity system.

Officials at the Government's Center for Disease control ... have described the spread of the disease as 'an impending epidemic' among haemophiliacs ....

In the past 10 months the disease has spread from the homosexual community to include haemophiliacs, Haitian immigrants, drug abusers, a handful of heterosexuals and some children. The cause remains baffling. One theory is that an infection agent is transmitted directly, either sexually or through contaminated blood products, in a similar manner to hepatitis B ....

Although no cases of AIDS have been reported from British haemophiliacs, the deaths of at least 10 American haemophiliacs, are now known to be caused by the disease following a survey of nearly 6000 haemophiliacs.<sup>106</sup>

**11.77** An article in the *New Scientist* of 3 February 1983 commented that there was a risk that AIDS was transmitted by blood products. It stated that the hunt for the cause of the disease:

[H]as now labelled as a prime suspect some unknown blood-borne virus.

....

In the last year, a task force under Dr Harold Jaffe at the Center for Disease Control in Atlanta, Georgia, has found seven cases of AIDS among haemophiliacs .... Jaffe believes that the spread of the disease may be connected with new preparations of factor VIII concentrate – the blood-clotting agent given to haemophiliacs – which are made up from blood from large numbers of donors, rather than one individual.

If this is correct, any patient in hospital who is given a blood transfusion could be at risk if one of the donors of the blood carries the virus.

No cases of AIDS among British haemophiliacs have been reported so far – even though 50 per cent of the factor VIII used in Britain comes from the US.<sup>107</sup>

---

<sup>103</sup> Day 17, pages 90–91

<sup>104</sup> Amended Witness Statement of Professor Charles Forbes [PEN.015.0254] at 0257

<sup>107</sup> 'AIDS – transfusion patients may be at risk', *New Scientist*. 03 February 1983 [DHF.001.7119]

**11.78** On 1 March 1983, a paper on AIDS was produced by the UK Haemophilia Centre Directors' Hepatitis Working Party.<sup>108</sup> It was sent to the DHSS on 11 April 1983. This paper summarised the position to that date, based on information from the CDC at Atlanta. Aetiology was explored, with the infectious agent theory being favoured as the most likely cause. The concluding paragraph stated that it was likely that batches of Factor VIII concentrate which might contain the AIDS agent had been in use since the beginning of 1980. The CDC had therefore requested the UK Haemophilia Centre Directors to report cases of AIDS which might be related to transfusion of US concentrate. A detailed list of possible symptoms, diseases and signs associated with AIDS formed part of the survey sent to all centre directors.<sup>109</sup>

**11.79** Dr Winter told the Inquiry:

I think by that stage all haemophilia clinicians were signed up to the infectious theory because of the evidence of the San Francisco child. There was no other construction you could put on that evidence. So I think these minutes are just reflecting – they are setting out the other theories and discounting them because of the new haemophilia data.<sup>110</sup>

**11.80** Despite Dr Winter's view, it is clear that in fact there was not unanimity by this stage. However, the view of the UK Haemophilia Centre Directors' Hepatitis Working Party can be taken to be broadly representative of opinion in the profession.

**11.81** In *The Annals of Internal Medicine* of March 1983, an editorial and a series of articles discussed the evidence available up to that time and lent further support to the transmissible agent hypothesis.<sup>111</sup> Dr Evatt and Dr Curran were two of the three authors of the editorial. It gave further information about the preparation of concentrates. In the US, plasma pools contained up to 22,500 individual donations and approximately 500,000 international units of anti-haemophilic factor. The average patient with severe haemophilia received 30,000 to 50,000 units per annum from 5 to 10 separate lots and was thereby exposed to tens of thousands of donors each year. Haemophilia patients receiving blood products were said to be at the highest risk of contracting AIDS. Substantially the same material was contained in the UK Haemophilia Centre Directors' Hepatitis Working Party report referred to in paragraph 11.78, above.

**11.82** In March 1983, Dr Peter Foster of the PFC (the Protein Fractionation Centre, the manufacturer of NHS blood products in Scotland) gave a series of presentations to haemophilia clinicians and haematologists in Edinburgh and Dundee.<sup>112</sup> He was somewhat guarded in expressing his opinion. He mentioned that AIDS might be caused by transmission of an infectious agent. In evidence, he said that at that time his perception of the risk had been somewhere between a possibility and a probability. He was not definitive, but thought that the risk should be taken into account by the PFC.<sup>113</sup> As an SNBTS scientist, that was a reasonable position to adopt at the time. An infectious aetiology was still

<sup>112</sup> Preliminary Report, para 11.113

<sup>113</sup> Dr Foster – Day 23, pages 10–11

not settled. The editorial in *The Lancet* of 2 April 1983, 'Acquired Immunodeficiency in Haemophilia', commented that the links with blood or blood products must be regarded as not proven.<sup>114</sup>

**11.83** The UK public health view as reflected by Dr Spence Galbraith, Director of the Communicable Disease Surveillance Centre (CDSC) in England and Wales, was set out in a letter to the DHSS in May 1983. He enclosed a paper setting out his views in support of the transmissible agent theory.<sup>115</sup> His view, which he supported by detailed discussion, was that the AIDS epidemic in the USA was probably due to a transmissible agent and that the agent was probably transmitted by blood and blood products.

### The comparative position in mid-1983

**11.84** Professor Lever commented on the competing theories at this time:

There were competing hypotheses as to what was causing the immunodeficiency, some of which had quite powerful advocates. I think ... the balance of opinion or the balance of evidence was in favour of an infectious agent at that stage. However, as one knows, the amount of distress and concern and worry, sometimes unnecessarily, that you can induce in people by raising the fear of an infectious agent in something like a blood product would be undesirable unless it was absolutely certainly the case, or as near certain as you could be that that was the case.

I think people would not necessarily have been very understanding had this turned out to be a false alarm and individuals had either bled or died by withdrawal of the clotting factors and then it having been found that there was not the threat which had been assumed.<sup>116</sup>

**11.85** Professor Ludlam said that the inferences in his studies in 1983 were confirmed when anti-HTLV-III (HIV) testing became available in late 1984 and all but two of the patients in the 1983 study were found to have been negative for HIV in 1982 and in 1983.<sup>117</sup>

**11.86** Professor Ludlam's work was to receive attention in June 1983. When Dr Foster reported on the World Federation of Haemophilia (WFH) and International Society on Thrombosis and Haemostasis (ISTH) meeting in June 1983, he recorded that some participants had attempted to make a number of points regarding features of haemophilia patients with T-cell abnormalities: in essence, North American studies correlated lowered helper-suppressor ratios with lifetime exposure to Factor VIII or with age, whereas European studies correlated the lowered ratios with use of imported concentrates and not with local concentrates. Many European participants were implying that USA products were 'bad news'. The North American response had been 'to cite Ludlam *et al*' and then to attack the validity of the data. The general feeling appeared to be that a low CD4/CD8 ratio in haemophilia patients would not necessarily indicate a pre-AIDS condition. Dr Foster's own

<sup>115</sup> Letter [MIS.001.0001]. Re-typed letter [MIS0010005]. See also Chapter 9, *Knowledge of the Geographic Spread and Prevalence of HIV/AIDS 1*, for further discussion of this letter.

<sup>116</sup> Day 26, page 92

<sup>117</sup> Day 19, page 40 (Of the two patients positive for HIV at that time, one died of AIDS, the other from bleeding.)

feeling had been of an attempt to suppress AIDS 'hysteria', although some of the more scientific criticism of the T-cell situation did appear to him to make some sense. He was at a disadvantage, as were others, in one respect: Dr Evatt had not submitted an abstract and delegates were left to make their own notes of his address.<sup>118</sup> He noted that Dr Evatt had explained that none of the known haemophilia cases had any other risk factor.

**11.87** There was a clash between Dr Evatt and Dr Aledort that reflected the depth of feeling at the time. Douglas Starr, in *Blood: An Epic History of Medicine and Commerce*, commented:

Bruce Evatt had been invited to speak, but he felt himself set up in a way. Though Aledort was supposed to give a brief introduction, instead he swung into a lengthy discourse on how little scientists knew about the disease. Evatt, when his turn came, felt he had to defend how much they *did* know.<sup>119</sup>

**11.88** The WFH was an influential body, comprising scientists, doctors, nurses and patients.<sup>120</sup> It concluded that there was insufficient evidence to cause changes in the treatment of haemophilia. Once more, however, the question appears to have turned on whether there was transmission by an infective agent to the exclusion of the risks inherent in the antigen overload theory.

**11.89** Professor Lever was asked when the early theories began to be disregarded. He responded that until the infectious agent had been found, theories like that would always have some degree of credibility. Once Montagnier and Barré-Sinoussi had identified something and 'certainly by the time Gallo had published', there was only a small fraction of individuals who still clung on to a theory of anything other than infection. He continued:

Up until that time I think it's a gradation. There was a gradual acceptance that it couldn't just be put down to immunological-based theories and that the epidemiology looked more and more like an infectious agent.<sup>121</sup>

### **May 1983: Identification of LAV**

**11.90** The continuing controversy in early summer 1983 initially paid little regard to the work of Montagnier and Barré-Sinoussi in France that was to become of real importance as the middle years of the decade passed. On 20 May 1983, an article appeared in *Science* reporting that the team of scientists at the Institut Pasteur in Paris had isolated a retrovirus, which they named lymphadenopathy-associated virus (LAV), from cultures of T-lymphocytes derived from the lymph nodes of a patient with signs and symptoms thought to precede AIDS.<sup>122</sup> There is more detailed discussion of this development in Chapter 29 *The Discovery of HIV and Development of Screening Tests*.

**11.91** The full significance of the French discovery was not widely understood in 1983 and later Montagnier was to recognise that the results remained controversial until Gallo

<sup>122</sup> Barré-Sinoussi et al, 'Isolation of a T-lymphotropic retrovirus from a patient at risk for acquired immune deficiency syndrome (AIDS)', *Science*, 1983; 220: 868–871 [LIT.001.0058]

and his group announced their discovery of HTLV-III in the spring of 1984.<sup>123</sup> Nevertheless, it seems likely that the article was known to Scottish scientists by 15 June 1983 and hardened opinion in favour of an infective agent, at least as a working hypothesis.<sup>124</sup>

**11.92** Reports of cases led to the identification of products possibly associated with transmission. Dr Foster's report from the WFH and ISTH meetings stated that of the 16 US cases one was a mildly affected Haemophilia B patient who also received two units of New York blood.<sup>125</sup> Of the 14 cases of AIDS reported to the UK CDSC by 31 July 1983, one was a haemophilia patient and it was noted that he had received Factor VIII imported from the USA.<sup>126</sup> There was growing apprehension that the disease was associated with commercial blood products from the USA. Dr Foster's report of the contribution of Dr Evatt included comments relevant to the present chapter. In summary, Dr Foster noted:

- The June 1983 figures at CDC showed that the total number of USA confirmed cases was marginally higher than would be predicted from an exponential growth, consistent with the view that AIDS is caused by a transmissible agent.
- Epidemiology strongly suggested a transmissible agent (AIDS had been found in spouses, male and female, siblings etc.)
- AIDS fell into two categories: those who developed KS and those who developed opportunistic infections.
- Haemophilia patients were in the group which developed opportunistic infections.
- AIDS was still located mainly in key urban areas in the USA (New York, San Francisco, Los Angeles) but the haemophilia cases were generally located in non-AIDS areas. This was strong evidence for transmission by Factor VIII.
- Common lots of Factor VIII concentrate seemed to be 'rare or non-existent'. Haemophilia patients who received material from two known Factor VIII lots prepared from plasma containing two AIDS donations had been followed for two years with no signs of AIDS at that stage.
- The haemophilia patient with AIDS in Cardiff received products from Armour and Immuno as well as NHS concentrates. Other suspected cases had received products from Hyland (reported from Israel) and Hyland and Immuno (reported from Sweden).<sup>127</sup>

**11.93** On 23 June, the recital of a Council of Europe resolution noted that AIDS 'may be caused by an infectious agent transmissible by blood and blood products'.<sup>128</sup>

<sup>123</sup> 'A History of HIV Discovery', *Science*, 2002; 298:1727 [LIT.001.3767] at 3768; Preliminary Report, para 8.83

<sup>124</sup> The Barré-Sinoussi article may have been the 'recent work' showing an association between AIDS and a human t-cell leukaemia virus referred to at a meeting on 15 June 1983 of the Factor VIII safety sub-committee: Minutes of FVIII Safety Sub-Committee Meeting held on 15th June 1983 [SNF.001.3730]. An alternative possibility is a different article in the same issue of *Science*: Gallo et al, 'Isolation of human T-cell leukemia virus in [AIDS]', *Science*, 1983; 220: 865–867

<sup>125</sup> Dr Foster appears to have prepared two reports: [SNF.001.3714] and [SNF.001.3712]; the one referred to is the latter of these.

<sup>126</sup> Haemophilia Centre Directors AIDS Investigation – Surveillance of AIDS Cases in Patients With Blood Coagulation Disorders [SNB.001.7556]. See reference to this case in Dr Craske's update in September 1983. The case was also highlighted in a letter to *The Lancet* of 19 November, 1983 [LIT.001.0413]

<sup>127</sup> Dr Foster's Memo [SNF.001.3712]

<sup>128</sup> Recommendation No R(83)–B of the Committee of Ministers to Member States on Preventing the Possible Transmission of Acquired Immune Deficiency Syndrome (AIDS) from Affected Blood Donors to Patients Receiving Blood or Blood Products [DHF.002.2149]

**11.94** On 13 July 1983, Dr Galbraith's paper of May<sup>129</sup> was discussed at a meeting of the Biological Products Sub-Committee of the Committee on Safety of Medicines.<sup>130</sup> It was minuted that the cause of AIDS was unknown but that an infectious aetiology seemed likely. The minute proceeded:

A previously unrecognised or new agent may be responsible, but repeated exposure to, or reactivation of, known agents, (eg CMV, EBV) may be involved. Heightened susceptibility may be an important factor, e.g. immunological deficiencies induced by unusual sexual practices or exposure to blood products. Based on the clinical evidence, transmissibility of the supposed agent(s) appears to be low, requiring intimate contact or introduction into the tissues.

Patients who repeatedly receive blood clotting-factor concentrates appear to be at risk, but the evidence so far available suggests that this risk is small. The risk appears to be greatest in the case of products derived from the blood of homosexuals and IV drug abusers resident in areas of high incidence (eg New York and California), and in those who repeatedly receive concentrates in high dosage.<sup>131</sup>

### Developments during the remainder of 1983

**11.95** Over the remainder of 1983, there were reports of increasing numbers of infections.<sup>132</sup> On 28 September, there was a meeting of the Central Blood Laboratories Authority.<sup>133</sup> It was noted that the Medical Research Council (MRC) had set up a working group on AIDS. The working group first met on 10 October 1983.<sup>134</sup> In their discussion of aetiology, there was a 'passing allusion' to the antigen overload hypothesis. The 'more widely held view' noted was that AIDS was due to a novel 'AIDS agent'. Retroviruses were considered and it was noted that HTLV was a possible candidate on the basis of its known tropism for T-helper cells.<sup>135</sup> The comment proceeded:

However a critical evaluation of the data led to the view that it was more probably an opportunist was unlikely [*sic* – likely]<sup>136</sup> to be the aetiological agent. The assumption that the agent was necessarily a virus was challenged and the need to keep an open mind on organisms such as protozoa was stressed.<sup>137</sup>

**11.96** The group was careful to reserve its opinions. It was said that the 'best and brightest' in the UK (at the MRC) were still very confused as to the causal agent. It was suggested that systematic antimicrobial therapy might provide leads on such agents. It was noted that blood product associated cases could enable some of these alternative hypotheses to be tested. Specifically in relation to epidemiology, but probably more generally, there was a lack of confidence in US studies which were thought to be insubstantial and not of the highest quality.

<sup>129</sup> Action on AIDS [MIS.001.0001]; Re-typed letter and paper [MIS.001.0005]

<sup>130</sup> Committee on Safety of Medicines – Sub-Committee on Biological Products, Minutes of the Meeting held on 13 July 1983 [MIS.001.0291]

<sup>131</sup> Ibid [MIS.001.0291] at 0292

<sup>134</sup> Minutes [SNF.001.3759]; Preliminary Report, para 8.54

<sup>135</sup> Tropism is the response of an organism to an external stimulus by growth in a direction determined by the stimulus. At this stage HTLV-III had not been discovered, but HTLV-I had been and was the subject of study.

<sup>136</sup> Notwithstanding the approval of the Minutes at the next meeting the Inquiry considers that the word 'unlikely' should read 'likely'

<sup>137</sup> Minutes [SNF.001.3759] at 3761

**11.97** Meantime, as events were to prove, UK patients were being infected with HIV. It is of interest to note the reasons for casting doubt on US epidemiological research:

The erasure of patients' names from the records held at the Centres for Disease Control in Atlanta as a result of political pressure would limit the ability of CDC to conduct proper epidemiological studies. The organisation of epidemiology in the United Kingdom was well suited to studying this problem. The importance of establishing such studies early in the emergence of disease was again stressed. Further emphasis was given to the concept of identifying early phases of the disease for testing aetiological hypotheses. It was emphasised that at this stage national collaboration was possible and indeed essential on items such as an AIDS case-control study and active surveillance ... The close liaison between clinical and laboratory medicine in the UK was again stressed as an important background for such work. Blood transfusion policy was discussed in relation to the possibility of using 'clean' donor panels for blood products.<sup>138</sup>

**11.98** This rather optimistic view of the situation in the UK is challenged by the difficulties in obtaining comprehensive data, not least caused by the insistence of haemophilia directors on the confidentiality of patient details (discussed in Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paragraph 10.101). This Inquiry has found no objective support for the MRC's relative lack of confidence in the CDC's epidemiological research.

**11.99** On 14 October 1983 the UK Central Blood Laboratory Authority's central committee for research and development in blood transfusion Working Group on AIDS in Relation to Blood Transfusion first met. The record of the meeting noted:

Epidemiological Features of HTLV infection

The epidemiological features of AIDS suggest that an infectious agent is responsible for the condition but as yet no aetiological factor has been unequivocally associated with the disease.<sup>139</sup>

**11.100** The paper proceeded to comment on evidence of HTLV infection in homosexuals and in AIDS patients, among other topics, and continued:

Recently two variant viruses have been found in association with a few AIDS patients. Cherman et al have described a retrovirus isolated from a French homosexual .... Recent evidence suggests that this virus is distinct from HTLV ... (Montagnier.Pers.Comm). A virus related to HTLV but distinct from HTLVI and HTLVII has recently been demonstrated in proviral form in a few AIDS patients.

The inherent difficulty in interpreting the significance of HTLV infection in AIDS patients is that these individuals are highly susceptible to a wide range of opportunistic infections, a category into which HTLV might fall. Furthermore the establishment of infections requiring intimate contact is likely to be favoured in populations with a high degree of sexual promiscuity, a social feature which appears to be common in AIDS victims.<sup>140</sup>

<sup>138</sup> Ibid [SNF.001.3759] at 3762–3763

<sup>139</sup> Minutes [DHF.002.4834] at 4838

<sup>140</sup> Ibid [DHF.002.4834] at 4839

**11.101** In the *British Medical Journal* of 15 October 1983, Karin Froebel and others (Professor Forbes' Glasgow group) reported on a study of changes in T-cell ratios in Scottish haemophilia patients exposed to Scottish and US Factor VIII concentrates.<sup>141</sup> They carried out a 'controlled' experiment to compare the cellular immunity of patients who had received solely Scottish product and a comparator group who were administered Profilate (Alpha) Factor VIII. Their conclusion was that:

Our results ... argue against a disease vector that is specific to American blood products. In terms of lymphocyte abnormalities, Scottish patients with haemophilia yield results that are consistent with those seen in the acquired immune deficiency syndrome and in acute viral infection. Whether these abnormalities in the T cell ratios ... are sufficient to render the patients immunodeficient and therefore, possibly, in a prodromal stage of the acquired immune deficiency syndrome, will become apparent as the patients are followed up clinically.<sup>142</sup>

**11.102** The paper was mentioned in *The Guardian* of 14 October 1983 in an article by Andrew Veitch, medical correspondent. He noted the findings and commented that, on the basis of the research, US Factor VIII appeared to be no more dangerous than the Scottish version. The headline and opening comments were:

Aids 'not imported in blood'

Fears that more haemophiliacs may contract Aids from contaminated US supplies of the blood clotting factor VIII will be calmed, at least temporarily, today.<sup>143</sup>

**11.103** The tone of the article was somewhat sceptical. Mr Veitch noted, without comment, emerging evidence in England that implicated US Factor VIII in the infection of haemophilia patients.

**11.104** The Glasgow paper appeared to accept the hypothesis that immunodeficiency might be diagnostic, in itself, of a prodromal state of AIDS. In that sense it was less cautious than Professor Ludlam's published views at this stage.

**11.105** The first World Health Organization (WHO) European conference on AIDS, entitled 'AIDS in Europe, Status Quo 1983', was held in Aarhus, Denmark between 19 and 21 October 1983.<sup>144</sup> The press release for the conference, dated 30 September 1983, noted that the AIDS epidemic continued to 'baffle' scientists.<sup>145</sup> It stated that the epidemiological evidence showed clearly that AIDS was contagious and that it was probably transmitted by blood contact. No infectious agent had so far been identified but a strong candidate was a C-type retrovirus.<sup>146</sup> Latency periods were thought to range from a few up to 18 months. It was still not clear what symptoms preceded fully-developed AIDS. Neither was there precise information about the number of AIDS victims who harboured the

<sup>145</sup> Press Release [SGF.001.0949]

<sup>146</sup> The class of 'C-type retroviruses' include avian leukosis virus and salmon lymphoma virus. It was later thought that HIV belonged to a different class of retroviruses, 'lentiviruses'. See Chapter 29 *The Discovery of HIV and Development of Screening Tests* at paragraph 29.4, footnote 6, for Professor Lever's view that more recent research suggests that, while certainly a retrovirus, HIV may not properly belong to the lentivirus genus, either.

putative infectious agent. In any case the very poor prognosis for AIDS victims made it essential to gather as much information as possible in a co-ordinated way, in order to help contain the disease through preventative measures and to set up international research projects.

**11.106** The fact that the meeting aimed to summarise the available information about the nature of prodromal (early) symptoms of AIDS and the effectiveness of the different therapeutic strategies reflected a low level of accepted knowledge of the fundamentals of the epidemic and the aetiology of the disease.

### End of 1983

**11.107** Dr Brian McClelland and Mr John Watt represented the SNBTS at a WHO Conference in Geneva between 22 and 25 November 1983.<sup>147</sup> Others attending included representatives from the CDC and Professors Montagnier, Leikola and Zuckerman. The draft report of the meeting was distributed on 14 December with a request for comments by 6 January 1984.<sup>148</sup> The aetiology of the disease was said to be unknown but the epidemiological pattern was said to be most consistent with a transmissible agent. Transmission appeared to occur by blood sharing; the most likely cause was a virus. Coagulation factor concentrates had been implicated and methods of inactivation were being developed but these could not be evaluated until the causative agent was discovered.

**11.108** The only new observation recorded was that an aetiological role for retroviruses had been considered because they were known to be capable of causing immunosuppression and neoplastic diseases (such as tumours) in animals after long latency periods. HTLV was suggested as a possibility.<sup>149</sup>

**11.109** There appear to have been two clear schools of thought at the end of 1983. There was no settled consensus as to the cause of AIDS or the diagnostic significance of the cellular abnormalities identified in laboratory tests. For many, the almost simultaneous appearance of acquired immune deficiencies in homosexuals, IV drug abusers and haemophilia patients pointed to a single transmissible agent. For others, there were cohort differences that distinguished the patient groups and suggested that different pathologies might be involved.

**11.110** The factors that were adduced in support of the antigen overload theory at this stage were:

- The low absolute and relative numbers of haemophilia patients with signs and symptoms of overt disease.
- The apparent absence of recorded disease in populations with a high exposure to imported commercial Factor VIII (notably in Germany).<sup>150</sup>
- Uncertainty whether there was one single cause of AIDS.
- The clinical differences between haemophilia patients and others with severe immune abnormalities.

<sup>147</sup> Dr McClelland was Director of the Edinburgh and East of Scotland Blood Transfusion Service. Mr Watt was Director of the PFC. See Preliminary Report, para 8.65 for a more extensive summary of the meeting.

<sup>148</sup> Draft Report [SNF.001.2575]; Covering Letter [SNF.001.2574]

<sup>149</sup> Dr McClelland's initial report for the Scottish Regional Transfusion Directors' meeting on 8 December 1983 [SNF.001.0552] contained no new data on transmission.

<sup>150</sup> Draft Report [SNF.001.2575] at 2609. It appears frequently to have been overlooked that Germany had reported a few cases of AIDS in haemophilia patients to the WHO by this time.

**11.111** There are several problems with this position. By no means all homosexual men contracting AIDS had KS and some developed PCP. Lack of evidence of KS in haemophilia patients did not distinguish them from the group of infected homosexuals as a whole. Further, to exclude KS from the constellation of conditions to which haemophilia patients might be exposed at this stage would have been speculative. The most that one could have said was that no cases had been diagnosed. Many individuals in both groups had PCP.

**11.112** The epidemiological evidence inevitably depended on the reliability of reports. But whereas by January 1983 there had been only eight cases out of a total haemophilia population in the USA of about 20,000, the total number increased during the year to 21.<sup>151</sup> The rate was increasing as it had in the case of homosexual men.

**11.113** Professor Ludlam thought that the antigen overload theory was still on the table but, increasingly, that appears to have depended on finding alternative explanations for emerging evidence favouring the transmissible agent theory.<sup>152</sup>

#### January to mid-May 1984

**11.114** It appears that the picture became clearer still in early 1984. There was a report in *The Annals of Internal Medicine* for January 1984 of AIDS in the elderly wife of a haemophilia patient.<sup>153</sup> Her husband had received Factor VIII concentrate and subsequently died from PCP and probable AIDS.

**11.115** The same issue of *The Annals of Internal Medicine* noted the case of the San Francisco child in a report of an NIH conference entitled 'Acquired Immunodeficiency Syndrome: Epidemiologic, Clinical, Immunologic, and Therapeutic Considerations'.<sup>154</sup> One of the contributors, Dr Edward Gelmann, commented on the arguments for and against the hypothesis suggesting that a retrovirus might be involved in the aetiology of AIDS. His conclusion was that:

The significance of the association between human T-leukemia virus and the acquired immunodeficiency syndrome is not known. There are no data to disprove that there may be an etiologic role for this virus in the syndrome. The elucidation of this role is hindered by the low levels and transient nature of the virus expression. Molecular analysis of the cloned viral genome from one of the patients described may shed further light on the significance and pathogenic potential of this isolate. On the other hand, human T-leukemia virus may represent another new or reactivated opportunistic infection in persons predisposed by the underlying immunodeficiency.<sup>155</sup>

**11.116** The evidence of T-leukemia virus infection in AIDS cases had come in particular from Dr Gallo's laboratory. So far as published, it was clearly not considered to be conclusive at this stage. However, by this time at least 11 possible cases of transfusion-associated AIDS, together with cases of sexual partners of risk group members and certain infants connected with risk group members, had been identified in addition to the groups

previously described. The previous, erroneous assumption that there was something intrinsic to homosexuality itself or other forms of sexual behaviour that was causally related to the syndrome had effectively been dismissed but this had not resolved the issue of aetiology.

**11.117** On 9 January 1984, the Blood Products Sub-Committee of the Haemophilia Society produced a paper reviewing blood products supply and related issues in the UK. On the topic of AIDS, the paper stated:

No discussion of blood products can be complete at present without referring to AIDS. Unfortunately facts are in very short supply. No infective agent has been identified for AIDS, and there is no reliable evidence that the disease is transmitted through blood products (although this still seems the most popular theory) ....

Certainly the immunological abnormalities which may be associated with AIDS are observable in haemophiliacs not exposed to commercial concentrates (e.g. in Scotland and Australia) ....

There is also a theory that the AIDS agent is closely associated with Hepatitis, the AIDS agent being in some way harboured by the hepatitis virus.<sup>156</sup>

**11.118** The letter to *The Lancet* by Professor Ludlam and others already referred to in paragraph 11.70 was cited in support of the reference to Scotland. The letter had noted that it seemed likely that immunosuppression observed in haemophilia patients resulted from infusion of foreign protein or a ubiquitous virus rather than a specific AIDS virus in Factor VIII concentrates. It did not say expressly that the abnormalities were those which might be associated with AIDS and Professor Ludlam was characteristically cautious in expressing his views. However, in general the paper reflected the continuing uncertainty about the aetiology of AIDS that was prevalent at the time among haemophilia doctors.

### *The balance of opinion*

**11.119** The approach adopted in the opinions of leading public health and transfusion doctors and blood product scientists was different. There were protagonists for and against an infective agent aetiology but the balance of opinion was, in general, in favour of an infective agent.

**11.120** On 12 January 1984, the *NEJM* published the results of a study by Curran and others of patients in the USA with AIDS and no recognised risk factors.<sup>157</sup> Patients who appeared to have been infected by blood transfusion were identified. At least one high-risk donor was identified for each of the seven cases in which investigation of the donors was complete. The authors concluded that their findings strengthened the evidence that AIDS might be transmitted in blood.

**11.121** An editorial in the same issue, by Joseph Bove, Yale University School of Medicine, advised caution in assessing the conclusions in the Curran paper. Having recited the data, he stated:

<sup>156</sup> Blood products Sub-Committee Paper [DHF.001.5151] at 5154

<sup>157</sup> Curran et al, 'Acquired Immunodeficiency Syndrome (Aids) Associated with Transfusions', *New England Journal of Medicine*, 1984; 310(2):69-75 [LIT.001.0695]

The apparent conclusion, and the one favoured by Curran et al., is that some cases of AIDS are caused by a blood-borne agent that is transmitted by transfusion. This conclusion also requires that there is a carrier state during which a person with infectious disease is healthy enough to be accepted as a blood donor. Although other epidemiological studies have also suggested such a carrier state, these transfusion-associated cases provide an opportunity to evaluate it more carefully and to study the critical aspect of recipient susceptibility.<sup>158</sup>

**11.122** The comment noted that the paper did not provide information about what happened to the recipients of other blood components from the suspect donors, whose donation would normally be channelled into component production. It proceeded:

If recipients of other components from the suspected donation remain healthy, one must either postulate an agent of low infectivity and assign major importance to host factors or question the basic assumption of blood-borne spread.<sup>159</sup>

**11.123** In the UK, a meeting was arranged by the National Institute for Biological Standards and Control (NIBSC), scheduled for 9 February 1984, to examine the infectious hazards of blood and blood products, with particular reference to hepatitis and AIDS.<sup>160</sup> The outcome of the discussion can only be regarded as inconclusive. Professor Tedder of the Middlesex Hospital Medical School posed the question whether AIDS could be caused by transmission of an infectious agent in blood and blood products. He commented that one possible explanation for the occurrence of AIDS in recipients of blood and blood products was due to a filterable agent, 'presumably a virus', but he noted that another possible explanation was 'an overwhelming of the immune system by repeated infusion of foreign (and possibly altered) proteins', concluding that 'the true explanation may lie between the two extremes'.<sup>161</sup> Dr Geoffrey Schild (NIBSC) suggested the possible importance of genetic susceptibility.<sup>162</sup> While some of the contributions appear to have proceeded on the hypothesis that AIDS could be transmitted by blood products, the record does not disclose an agreed answer to Professor Tedder's question.

### *Growing concern*

**11.124** There was growing concern in Scotland. By letter dated 15 February 1984 Professor John Cash, Medical Director of the SNBTS, wrote to Dr Albert Bell at the Scottish Home and Health Department (SHHD). He suggested that a UK group should be formed for coordinating research into blood transfusion and AIDS. He said:

[T]here should be formed a single UK group responsible to the Departments of Health for co-ordinating research in the area covering the interface between blood transfusion and AIDS. This group should have representatives of existing smaller groups already in existence – haematologists and haemophilia centre directors and of the SNBTS Directors.<sup>163</sup>

<sup>158</sup> Bove, 'Transfusion Associated Aids – A Cause for Concern', *New England Journal of Medicine*, 12 January 1984 [LIT.001.0702]

<sup>159</sup> Ibid [LIT.001.0702]

<sup>160</sup> Draft Minutes [SNB.004.8628]; Preliminary Report, para 8.75

<sup>161</sup> Ibid [SNB.004.8628] at 8630

<sup>162</sup> Ibid [SNB.004.8628] at 8635

<sup>163</sup> Letter [SNB.004.8639]; Preliminary Report, para 8.77

**11.125** The major areas of research proposed were listed and Professor Cash asked Dr Bell to bring those matters to the attention of the appropriate authorities.

**11.126** Meanwhile events were proceeding apace. Dr Evatt and others (including Dr Curran) returned to the subject in *The Annals of Internal Medicine* in April 1984.<sup>164</sup> In all but two of the 22 haemophilia cases examined by this time the standard risk factors had been excluded. The common factor was exposure to Factor VIII or Factor IX concentrates and all but one had also received other blood components. The discussion commented that the hypothesis that AIDS developed in the patients as a result of an infectious agent transmitted by blood products seemed logical. That had been Dr Evatt's view from early 1982. It seems unlikely that it would have been sufficient of itself to overcome the reservations of others. At this point, before publication of Gallo's work, the issue was clearly unresolved to general expert acceptance, at least in the haemophilia community.<sup>165</sup>

**11.127** The views of adherents of the 'antigen overload' theory among haemophilia clinicians at this time were reflected in a paper prepared by Professor Ludlam in 1990.<sup>166</sup> It contained a comprehensive analysis of the competing theories, and served to underline the state of uncertainty among haemophilia clinicians, as seen by Professor Ludlam, about the aetiology of AIDS until Gallo's publication. The paper was prepared for pending litigation in England and Wales.<sup>167</sup> However, it reflected Professor Ludlam's published research and he confirmed that it reflected the way of thinking at the time. In summary, as an alternative to a viral aetiology, immune abnormalities observed in asymptomatic haemophilia patients might be due to the following:<sup>168</sup>

- A previously undescribed feature of haemophilia.
- Chronic liver disease.
- Large amounts of foreign proteins in plasma preparations.

**11.128** Professor Ludlam summarised the evidence for the immune abnormality being due to blood products and not a virus and the contrary proposition that the immune changes could have been due to a putative AIDS virus, repeating the discussion already dealt with that had evolved over time, particularly as reflected in his own research. He said:

I think one of the things that we were just wondering ... was that maybe the AIDS in people with haemophilia was actually of a different aetiology from that in gay men ....

....

[M]aybe haemophilia as a whole was sliding into AIDS because of all the concentrate we were using. Quite separate from HIV or a putative virus.

Q: Just looking on AIDS almost as an end stage, as it were, in the progressive demolition of the immune system?

A. From Factor VIII concentrate per se or the proteins, the contaminant.<sup>169</sup>

<sup>164</sup> Evatt et al, 'The Acquired Immunodeficiency Syndrome in Patients with Hemophilia', *Annals of Internal Medicine*, 1984; 100:499-504 [LIT.001.0689]

<sup>166</sup> Professor Ludlam – Human Immunodeficiency Virus Infection in Haemophiliacs [PEN.015.0385] 30 October 1990

<sup>167</sup> Day 18, page 20

<sup>168</sup> Day 18, page 143, Professor Ludlam – Human Immunodeficiency Virus Infection in Haemophiliacs [PEN.015.0385] at 0401–0402

<sup>169</sup> Day 18, pages 149–150

**11.129** This answer is revealing. It suggests that, as an adherent of the antigen overload theory, Professor Ludlam had in mind that there was no significant clinical difference between the acquired immune deficiency syndromes in haemophilia patients and other groups and that each might be a progressive and potentially fatal complication in haemophilia. Fundamental to the theory was the hypothesis that factor concentrates by themselves were contributing to the development of serious acquired immune deficiency.

**11.130** Professor Ludlam was pressed on the question whether physicians examining the problem could have thought that antigen overload was the whole explanation of immune abnormalities in haemophilia patients. He said:

I think that became increasingly less tenable with the unfortunate case reports of a spouse and a child of a haemophiliac developing AIDS ... Because that was evidence of a presumed sexually transmissible agent, furthermore, sadly being passed to the child.<sup>170</sup>

**11.131** Professor Ludlam was referred to an article by Drs Barbara and Tedder published in October 1984.<sup>171</sup> The article suggested that 'little significance should be attached to reports of abnormal lymphocyte profiles in haemophiliacs'. He ultimately accepted that 'by October 1984, there was little doubt that HTLV-III was the cause of AIDS', including in people with haemophilia.<sup>172</sup>

### *The 'antigen overload' theory in retrospect*

**11.132** In retrospect it appears that the antigen overload theory was not a satisfactory answer to the question whether there was AIDS associated with haemophilia. On the face of it, Dr Aledort's view, and the development of the antigen overload theory generally, led to the conclusion that heavy and prolonged use of factor concentrates, and in particular Factor VIII, could be expected, in some cases, to damage the blood disorder patient's immune system in a way similar to the damage found in homosexual men who were exposed to the risk of progression to AIDS. That had to include the possibility of a fatal prognosis in some cases at least. It provided an explanation for the development of immune abnormalities in some patients, due solely to the administration of factor concentrates, but implicit in it was a risk of progressive damage. That process might result in an immune deficiency state indistinguishable from that in asymptomatic homosexual patients who were at risk of AIDS. Without evidence of relative rates of progression, the outcome for the patient might be the same whatever the aetiology of the cellular immune deficiency.

**11.133** Further, the possibility of antigen overload as a causative factor could not exclude the concurrent possibility of infection transmitted in blood and blood products, with a fatal prognosis in some cases. The two aetiologies postulated were not mutually exclusive. The positive risk could not exclude the increasing probability that haemophilia patients might also develop AIDS due to viral transmission. At best it was an additive risk. At worst it was an aggravating feature that could increase the threat to the patient exposed to an infective agent.

<sup>170</sup> Day 18, page 155. Ragni et al, 'Acquired immunodeficiency syndrome in the child of a haemophiliac', *The Lancet*, 19 January 1985 [LIT.001.5042]

<sup>172</sup> Day 19, pages 5 and 7

**11.134** Less than three years had passed from publication of the first cases of AIDS, however. Despite intensive research and debate, there was no consensus as to the cause of the immune abnormalities observed in the haemophilia community, where they affected patients with severe Haemophilia A in particular. There was ample scope for continuing research and debate. How that might have developed would be a matter of pure speculation, however, as there was about to be a major change in direction.

### **May to October 1984: identification of HTLV-III**

**11.135** Dr Gallo and his group announced the discovery of HTLV-III on 23 April 1984 at a press conference in Washington.<sup>173</sup> As described in Chapter 29, *The Discovery of HIV and the Development of Screening Tests*, they concluded that HTLV-III might be the primary cause of AIDS and found antibodies to HTLV-III in a majority of patients with AIDS, thus opening the way to future testing of those infected by the virus.

**11.136** With the development of HTLV-III testing, following US research based on Dr Gallo's work, further cases of infection emerged and the discovery laid the basis for the general consensus that has prevailed ever since.

**11.137** Gallo's finding that HTLV-III caused AIDS is discussed in more detail in Chapter 29, *The Discovery of HIV and the Development of Screening Tests*. Confirmation of his findings was provided by Jay Levy and others, writing on the recovery of retroviruses from Factor VIII concentrates and processes to inactivate them.<sup>174</sup> Levy's findings on virus inactivation were, in turn, referred to in the US CDC update on AIDS in persons with haemophilia published in the *MMWR* of 26 October 1984.<sup>175</sup> For present purposes, the ability to infect Factor VIII concentrate with the AIDS virus, freeze dry it and thereafter heat it to reduce residual virus titre to an undetectable level were important stages in proof of a viral aetiology for AIDS. Nine patients were discussed. They had no risk factors for AIDS other than haemophilia therapy. The Editorial Note in the *MMWR* stated:

[T]he occurrence of nine cases with no known risk factor or exposure other than the use of factor VIII preparations implicates these products as potential vehicles of AIDS transmission.<sup>176</sup>

**11.138** These were significant findings. As a practical matter, after Gallo, work in the USA turned towards identification of infection in individuals and virus inactivation in manufacture.

### **The view in the UK in 1984**

**11.139** Even after the reports from Montagnier and Gallo, there continued to be comments published in the UK suggesting that immunological compromise in patients with haemophilia might be due to the repeated challenge of the immune system inherent in administration of Factor VIII concentrates manufactured from large pools. On 30 June 1984 *The Lancet* published an article by Dr Robert Carr and others (Professor Ludlam's Edinburgh group), related to a study of 47 patients with haemophilia who had been

<sup>173</sup> Preliminary Report, para 8.84

<sup>175</sup> 'Update: Acquired Immunodeficiency Syndrome (AIDS) in Persons with Hemophilia' *MMWR*, 1984; 33(42):589-591 [PEN.013.0186]

<sup>176</sup> 'Update: Acquired Immunodeficiency Syndrome (AIDS) in Persons with Hemophilia' *MMWR*, 1984; 33(42):589-591 [PEN.013.0186] at 0187

treated exclusively with SNBTS Factor VIII and Factor IX concentrates.<sup>177</sup> In Haemophilia A patients, the number of T-cells was depressed, resulting in a reduction of the helper/suppressor ratio in about half the patients. In Haemophilia B, the helper/suppressor ratio was also depressed, attributable to a slight increase in the suppressor number and a slight decrease in the helper number. It was suggested that these immunological abnormalities resulted from transfusion of foreign proteins in blood products rather than from an infective agent in the blood products giving rise to AIDS. It was also commented that at least a year had passed since the most recent batch of plasma used to prepare these concentrates had been collected.

**11.140** The final comment in the article was:

Furthermore, the relation between the lymphocyte subset abnormalities in symptomless haemophiliacs and the likelihood of eventual frank AIDS remains unclear although it may be connected with HLA status.<sup>178</sup>

**11.141** The article must have been written and presented for publication some months earlier than its date (30 June) and Gallo's discovery would not have been known to the authors. It forms an important bridge between Professor Ludlam's earlier 1983 letter and the discovery in late 1984 of the infection of the Edinburgh Cohort (a group of Edinburgh haemophilia patients infected by NHS products, discussed in Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*). Briefly, at this date it remained an acceptable view among certain experts in the UK that full-blown AIDS in haemophilia patients might be the end-stage of progressive immune compromise caused by something other than a specific AIDS infective agent, an unidentified component of concentrates or a non-specific effect of foreign proteins.

**11.142** Therefore, at least until June 1984 some haemophilia clinicians clearly remained sceptical of the claims that AIDS was caused by a transmissible virus. Some in the scientific community took a different approach and researched the development of a laboratory test, as had happened in the USA.

**11.143** On 7 July 1984 *The Lancet* published a letter by Mads Melbye and others.<sup>179</sup> A study of 22 haemophilia patients from Denmark who had been treated with Factor VIII concentrate purchased from US and European commercial sources demonstrated a high prevalence of antibodies to LAV: 14 of the 22 were positive.<sup>180</sup> Clinicians caring for haemophilia patients were advised to consider alternative forms of therapy for new patients not yet exposed to 'Cryoprecipitate concentrate', factor concentrate in UK nomenclature. The authors stated that, until screening tests or inactivation techniques were in widespread use, commercially available cryoprecipitate products should be considered as 'probably contaminated'.

**11.144** This was followed by a letter in *The Lancet* dated 18 August 1984 by Rosemary Ramsay and others (including Dr Evatt) of the CDC giving additional information about a number of US cases. They argued that the serological data described, indicating a high risk

<sup>177</sup> Carr et al, 'Abnormalities of circulating lymphocyte subsets in haemophiliacs in an AIDS-free population', *The Lancet*, 1984; 1431-1434 [LIT.001.0425]; Preliminary Report, para 8.86

<sup>178</sup> Carr et al, 'Abnormalities of circulating lymphocyte subsets in haemophiliacs in an AIDS-free population', *The Lancet*, 1984; 1431-1434 [LIT.001.0425] at 0428. HLA, human leukocyte antigen, is the immune system's recognition protein. It is discussed in more detail, in the context of HCV, in Chapter 13, *Knowledge of Viral Hepatitis Now*.

<sup>179</sup> Melbye et al, 'High prevalence of lymphadenopathy virus (LAV) in European haemophiliacs', *The Lancet*, 1984; 40-41 [LIT.001.0423]

<sup>180</sup> Interestingly, when the research was published in December, it was said that 59% of the Danish patients were infected. 59% of 22 would be 13, not 14.

of exposure to LAV for heavy users of Factor VIII concentrate, supported the contention that LAV was transmitted by some blood products. They studied 25 Haemophilia A patients and four with Haemophilia B, none of whom had symptoms associated with AIDS:

Haemophilia A patients who were seropositive for LAV had used significantly more factor VIII concentrate than had patients sero-negative for LAV. This association would be expected if factor VIII concentrates contain LAV or its proteins. In contrast, the haemophilia patients with AIDS had a significantly lower antibody prevalence, perhaps because patients with AIDS have a declining antibody response to antigen despite paradoxically higher levels of circulating immunoglobulins. 4 patients with haemophilia B were negative for LAV antibody and had normal cellular immunity. Patients with haemophilia B, in general, have not been found to have the degree of immune abnormalities seen in haemophilia A.

These serological data, indicating a high risk of exposure to LAV for heavy users of factor VIII concentrate, support the contention that LAV may be transmitted by some blood products.<sup>181</sup>

**11.145** Although not published until October 1984 in *Clinics in Haematology*, the transfusionist John Barbara and virologist Richard Tedder had written in about May or June that:

The characteristics of agents lending themselves to transmission by blood or blood products centre around their presence in blood, or its components, which has been taken from *apparently healthy donors*. Thus these agents often will have a combination of a long incubation period with a prolonged and high-level viraemia.<sup>182</sup>

**11.146** It was inferred that agents transmitted by blood and blood products must have a 'silent period' because the donor appeared healthy when blood was given. In relation to HTLV-III, the paper noted the cases of possible transmission of AIDS by transfusion and continued:

The transmission of AIDS by pooled clotting factor concentrates is less controversial. Since, as a group, haemophiliacs are well studied, it is unlikely that there should have been an illness like AIDS unrecognized before 1980. Little significance should be attached to reports of abnormal lymphocyte profiles in haemophiliacs; nevertheless there is no doubt that there have been deaths of haemophiliacs due to AIDS in the absence of other established risk factors and that, unlike those associated with transfusion, these cases were scattered throughout the USA. In addition there is a report which seems to have identified the transmission of AIDS from a haemophiliac (asymptomatic at that time) to his wife.<sup>183</sup>

**11.147** The paper went on to note the isolation and characterisation of LAV/HTLV-III and the likely aetiological link to AIDS.

<sup>181</sup> Ramsey et al, 'Antibody to Lymphadenopathy-Associated Virus in Haemophiliacs With and Without AIDS', *The Lancet*, 1984 [LIT.001.0421] at 0422

<sup>182</sup> Barbara and Tedder, 'Viral Infections Transmitted by Blood and its Products', *Clinics in Haematology*, October 1984; 13/3 [LIT.001.3739] (emphasis in original)

<sup>183</sup> Ibid [LIT.001.3739] at 3749

**11.148** Professor Ludlam was asked to comment on the statement that little significance should be attached to reports of abnormal lymphocyte profiles in haemophilia patients. He said:

They are virologists and until the virus was identified and the antibody test developed, there was no other way of studying this condition other than by immune tests. These were patients who presented, when they developed AIDS, with profound immune deficiency and they were therefore investigated for immune deficiency with laboratory investigations.

....

Q. Yes, but I suppose the point they seemed to me to be making was that, firstly, this is plainly being written after the work by Gallo in the earlier part of 1984, which had linked AIDS and HTLV-III, and they seem to be saying, firstly, that, as far as they are concerned, the hunt is over, and the agent which is causing AIDS in people of homosexual orientation and also people with haemophilia, the hunt is over. Is that what they are saying?

A. I think by October 1984 there was little doubt that HTLV-III was the cause of AIDS ... I'm very happy to accept that. However, we don't know or we didn't know until the antibody test was produced, just how many people might have been infected. We don't know whether everyone was equally susceptible. It may be those who had abnormal immune tests were more susceptible to the virus when exposed to it. So I'm happy – very happy to agree.

....

Q. I can certainly understand, professor, the point you make, that there were many unanswered questions, and indeed even today there seem still to be unanswered questions, but your acceptance that you indicated a moment ago that by the autumn of 1984 that this virus, HTLV-III, was the cause of AIDS, including in people with haemophilia; does your acceptance extend to that?

A. Yes.

Q. Right. The point that Drs Tedder and Barbara make in this paragraph however, about it being unlikely that there should have been an illness like AIDS in people with haemophilia caused by some other phenomena, that was a valid point even in 1983, was it not?

A. Yes.<sup>184</sup>

### *Autumn 1984: a viral aetiology*

**11.149** Given Professor Ludlam's prominence in the development of alternative theories, the autumn of 1984 can be seen as the point at which a viral aetiology for AIDS was established, notwithstanding that there remained unanswered questions. It followed that some patients receiving factor concentrate therapy for haemophilia and other coagulation deficiencies were known at that stage to have been exposed to the risk of transmission of HTLV-III/HIV. Attention began to focus on the progression of disease from infection.

---

<sup>184</sup> Day 19, pages 4–7

**11.150** On 1 September 1984, *The Lancet* published the article by Dr Rachanee Cheingsong-Popov and others (including Professor Tedder). HTLV-III and LAV-1 were indistinguishable. The high incidence of HTLV-III antibodies in haemophilia patients found in this and other studies had to be set against the relatively low incidence of overt AIDS in this risk group so far – roughly one per thousand haemophilia patients in the UK.

**11.151** The article defined the hypothesis for the cause of AIDS in these terms:

Recent evidence has strongly implicated newly identified retroviruses as the cause of AIDS and PGL.<sup>185</sup> These viruses have been termed lymphadenopathy-associated or immunodeficiency-associated virus (LAV/IDAV) and human T-lymphotropic virus type III (HTLV-III), and they seem to have more similarities than differences. To date the evidence implicating them aetiologically comprises a high frequency of virus isolation from AIDS and PGL patients and high prevalence of specific antibody in these subjects. A notable feature of these retroviruses is their tropism for the T “helper” (T4<sup>+</sup>) lymphocytes, which typically are depleted in AIDS patients.<sup>186</sup>

**11.152** The detection of HTLV-III antibodies in all but one of the AIDS patients studied was said to strengthen the evidence for an aetiological relationship to AIDS. The prevalence of HTLV-III seropositivity in PGL patients was said to confirm the notion that HTLV-III was not the cause only of AIDS but was also the cause of PGL in epidemiologically related risk groups.

**11.153** The authors commented that even if the causal relationship with AIDS and PGL was established, as the evidence strongly suggested:

[W]e should not assume that these disorders will develop in all patients infected with this retrovirus .... Although it is too early to draw firm conclusions, it seems possible that overt disease will not develop in at least some, and perhaps the majority of seropositive subjects.<sup>187</sup>

**11.154** An apparent carrier state was also described.

**11.155** The article made reference to an accompanying paper by Professor Brian Gazzard and others. That paper referred to earlier US research relating to sexual contacts of AIDS patients, the recent discovery of LAV/HTLV-III and the accompanying paper supporting the aetiological association with AIDS/PGL. The main object of the study was explained as being:

[T]o observe the clinical spectrum of disease in men who had had sexual contact with AIDS or PGL patients, and to correlate development of symptoms with HTLV-III positivity.<sup>188</sup>

<sup>185</sup> Persistent generalised lymphadenopathy: enlarged lymph nodes, a condition that occurs frequently in the latent period of HIV infection.

<sup>186</sup> Cheingsong-Popov et al, 'Prevalence of antibody to human T-lymphotropic virus type III in AIDS and AIDS-risk patients in Britain', *The Lancet*, 1984; 477–480 [LIT.001.0417]; Preliminary Report, para 8.92

<sup>187</sup> Cheingsong-Popov et al, 'Prevalence of antibody to human T-lymphotropic virus type III in AIDS and AIDS-risk patients in Britain', *The Lancet*, 1984; 477–480 [LIT.001.0417] at 0419

<sup>188</sup> Gazzard et al, 'Clinical Findings and Serological Evidence of HTLV-III Infection in Homosexual Contacts of Patients with AIDS and Persistent Lymphadenopathy in London', *The Lancet*, 1984; 480–483 [DHF.002.5914]

**11.156** They reported that several of the group's findings were consistent with the hypothesis that HTLV-III was the sexually transmitted agent responsible for both AIDS and PGL and that it might be associated in certain cases without symptoms. It was a very early description of the natural history of the disease.

**11.157** On 11 September 1984, the SNBTS Directors met.<sup>189</sup> Dr McClelland reported that Professor Tedder had acquired a significant quantity of reagents from the USA and was establishing anti-HTLV-III assays.<sup>190</sup> The work of the English scientists was intimated to all of the Directors in Scotland at this stage.

**11.158** Within Scotland, there was active exchange of data and other information between the SNBTS in Edinburgh and scientists in Glasgow following a letter from Dr Perry to Dr Froebel at the GRI on 15 October 1984 in which Dr Perry asked for information about Glasgow data on HTLV-III and offered samples of Factor VIII for screening purposes.<sup>191</sup> Scottish scientists were also collaborating actively with colleagues abroad in developing knowledge of the disease and its prevalence.

### October to December 1984: growing awareness

**11.159** Knowledge of AIDS among haemophilia patients, of its prevalence and aetiology, continued to accumulate in this period, in the USA and in the UK. Evidence of transmission became more clearly focused in the UK on 23 October 1984. Dr Craske of the Public Health Laboratory Service (PHLS), Withington Hospital, Manchester, circulated a letter advising that a batch of Factor VIII concentrate produced by the Blood Products Laboratory (BPL, the English manufacturer of NHS blood products) had been found to be infected with HTLV-III. He warned of the possible risk of infection with HTLV-III and subsequent development of AIDS.<sup>192</sup> Professor Cash, Professor Ludlam and Dr Perry, amongst others, received copies of the letter.<sup>193</sup>

**11.160** Dr Craske's letter of 23 October 1984 provided a direct sequential link between infection in donated blood included in a plasma pool and transmission of AIDS to haemophilia patients and was, at least, highly persuasive evidence of a causal relationship. He stated:

You will have already heard that one of the donors who contributed to the plasma pool used in the manufacture of the batch of factor VIII ... was recently admitted to hospital with clinical features consistent with the diagnosis of AIDS. I am afraid that this has now been confirmed. The patient has developed Pneumocytosis carinii pneumonia and two specimens of serum collected in September and October 1984 have been found to be positive for antibody to HTLV-3 by competitive radioimmunoassay (RIA).

....

From studies already underway on recipients of batches of factor VIII transfused to the two haemophilia A patients who contracted AIDS in 1983, we have already provisionally identified one batch of factor VIII which was transfused to one of the AIDS patients and was associated with seroconversion to HTLV-3

<sup>193</sup> Circulation stamp dated 13 November [SNF.001.4020]

antibody positive in seven out of thirteen recipients. One of the patients who acquired HTLV-3 infection subsequently developed AIDS, a second developed thrombocytopenia, and the other five have remained symptomless.<sup>194</sup>

**11.161** Dr Craske commented that further research was required to confirm the association of HTLV-III infection and transfusion. However, against the background of earlier published work, this letter was significant in giving wide publicity within the medical and scientific community in the UK to the risk of transfusion-transmitted HTLV-III in haemophilia patients. It helps to identify a time from which there was, or should have been, general acceptance of risk associated with factor concentrates. There were, in addition, other contemporaneous sources of information pointing in the same direction and medical practitioners began to consult scientists to investigate the incidence of infection in their own patients (see Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paragraphs 10.3–10.5). The results of testing by Professor Tedder and his colleagues of samples submitted by clinicians demonstrated the association of HTLV-III infection with the transfusion of factor concentrates.

### Developments in 1985

**11.162** In January 1985, '[AIDS] – an overview' by James Gracie and others was published in the *Scottish Medical Journal*.<sup>195</sup> The authors, Dr Gracie, Dr Froebel, Dr Madhok, Professor Lowe and Professor Forbes, practised at the Regional Haemophilia Centre, GRI. The article presents a picture of the generally held views at that Centre at the time of its preparation (December 1984). Overall, the authors stated that it seemed certain that a specific transmissible agent was responsible for AIDS. Other theories were dismissed.

**11.163** Emerging data on AIDS in patients who did not belong to any at-risk group but who had received blood transfusions were commented on as having serious implications. It had become necessary to look at the safety procedures used in obtaining blood and blood products.<sup>196</sup> The article made no mention of the Edinburgh Cohort. It cannot be taken to reflect the opinion among experts throughout Scotland but it does show a level of understanding of the wider context. The exposure of haemophilia patients to risk was clearly documented.

**11.164** The *MMWR* dated 11 January 1985 published provisional public health recommendations on screening donated blood. By way of background, it stated:

Evidence has shown that a newly recognised retrovirus is the cause of AIDS. Although this virus has been given several names ... it is referred to as HTLV-III in this discussion.

....

Epidemiologic data suggest that the virus has been transmitted through intimate sexual contact; sharing contaminated needles; transfusion of whole blood, blood cellular components, plasma, or clotting factor concentrates that have not been heat treated; or from infected mother to child before, at, or shortly after the time of birth.<sup>197</sup>

<sup>194</sup> Letter [SNF.001.4020]

<sup>195</sup> Gracie et al, 'Acquired Immune Deficiency Syndrome – An Overview', *Scottish Medical Journal*, January 1985; 30/1 [LIT.001.0829]

<sup>196</sup> Ibid [LIT.001.0829] at 0833

<sup>197</sup> 'Provisional Public Health Service Inter-Agency Recommendations for Screening Donated Blood and Plasma for Antibody to the Virus Causing Acquired Immunodeficiency Syndrome', *MMWR*, 11 January 1985 [SNB.004.9195] at 9195–6

**11.165** In the public health context in the USA, AIDS was unequivocally held to be caused by HTLV-III.

**11.166** On 9 February 1985, a letter written by Professor Arthur Bloom was published in *The Lancet*.<sup>198</sup> It was concerned primarily with clinical practice and relative risks associated with the use of concentrates but it acknowledged finally and expressly the infection of British Factor VIII with HTLV-III and the risk of transmission.

**11.167** On 3 August 1985 *The Lancet* published the Royal Infirmary of Edinburgh (RIE) preliminary study of Edinburgh haemophilia patients ('the Edinburgh Cohort') referred to in Chapter 10 *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*, paragraphs 10.57–10.60. This was a milestone document. The authors of the report were Professor Ludlam, Dr Tucker, Dr Steel, Professor Tedder, Dr Cheingsong-Popov, Professor Weiss, Dr McClelland, Ms Philip and Dr Prescott. The article stated:

As part of the continuing assessment of our haemophiliacs, we have now observed that sixteen of our patients acquired anti-HTLVIII during 1984; all but one of these patients had received a common batch of SNBTS factor VIII concentrate.<sup>199</sup>

**11.168** The text acknowledged that substantial evidence had accumulated that the most likely cause of AIDS was HTLV-III/LAV infection. Re-testing stored samples had demonstrated that the patients' sub-set irregularities (identified in the spring of 1983) prior to transfusion of the infected batch were not associated with HTLV-III infection. This demonstrated that the abnormal T lymphocyte subsets reported in 1983 were a result of the intravenous infusion of Factor VIII and not HTLV-III infection but it also suggested a relationship between CD4/CD8 ratios and the exposure of patients to HTLV-III infection: the lower the ratio, the greater the incidence of HTLV-III antibodies.<sup>200</sup> The absence of apparent seroconversion in a substantial number of patients was thought to be due to a range of factors including the concentration of antibodies; the immunological status of the individuals; the absence of viral infection; or replication of the lymphocyte cells.<sup>201</sup>

**11.169** The paper acknowledged the reality for Scottish clinicians and patients: HTLV-III was the most likely cause of AIDS and was transmitted by blood products. Information about these cases and contemporaneous English experience put the issue of risk to patients beyond question, as Professor Bloom's letter in *The Lancet* of February 1985 shows.

**11.170** More widely, there was further evidence. The *NEJM* of 21 February 1985 published an article by Dr Evatt and others describing research into the incidence of antibodies to HTLV-III/LAV in haemophilia patients in California, Georgia, New York and Texas by testing stored serum samples from several centres. There were no seropositive patients in the 1968 and 1969 samples and there was only one seropositive patient in 1978 in California. They also found that a seropositive response was related to the amount of Factor VIII used.<sup>202</sup>

## 1986 and beyond

**11.171** Between 11 and 13 February 1986 there was a conference in Newcastle on AIDS sponsored by the Haemophilia Society. The introduction to a paper presented (by Dr Philip Mortimer, PHLS)<sup>203</sup> at the conference stated that:

There is convincing evidence available from studies involving donor-recipient pairs that the HTLV-III/LAV virus can be transmitted by the transfusion of infected blood and blood products.<sup>204</sup>

**11.172** It was also narrated that during 1984 the causative virus for AIDS was recognised as HTLV-III/LAV and that there was a significant correlation between the antibody to HTLV-III/LAV and patients with AIDS.<sup>205</sup> In his paper, Dr Mortimer said that of 4000 haemophilia patients in the UK, 25% were positive for antibodies to HTLV-III.<sup>206</sup> Only 0.006% of transfusion recipients were positive for antibodies to HTLV-III.<sup>207</sup> Blood donor screening had shown that one in 45,000 donors was positive.<sup>208</sup>

**11.173** It is clear that by this date there was general acceptance of a causal association between some infected blood products and the development of HTLV-III/LAV and AIDS in haemophilia patients.

**11.174** Between 14 and 16 April 1986, the WHO held a meeting in Geneva, on the safety of blood and blood products in relation to AIDS. A report on the meeting was prepared by the World Hemophilia AIDS Center.<sup>209</sup> Prior to the meeting, WHO officials and plasma fractionators met to discuss current LAV/HTLV-III inactivation methods. Thirty-three countries were represented at this meeting, principally by staff from blood banking or blood transfusion facilities and a large staff of participants from the secretariat of the WHO under the direction of John Petricciani, Chief of Biologicals.

**11.175** The meeting began with an overview of infection with LAV/HTLV-III virus, in which information was presented regarding the recognition and identification of two new retroviruses termed LAV-2 and HTLV-IV. The speaker representing Professor Montagnier stated that the AIDS virus was the first human lente virus (otherwise 'lentivirus') and was comparable to the visna virus in sheep.<sup>210</sup> The envelope gene in the visna virus is highly variable. The two new viruses had been termed LAV-II (isolated from two patients in West Africa) and HTLV-IV (isolated in Kakar, also in West Africa). These two viruses were not identical, although they had some cross-reactivity with LAV-1 and HTLV-III respectively. The new terminology apparently would be HIV-1 (human immunodeficiency virus 1), which was equivalent to LAV-1, to HTLV-III, and to ARV (AIDS retrovirus). HIV-2 was equivalent to LAV-2 (from West Africa). HTLV-IV remained to be classified. The phylogenetic tree (see Chapter 10, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 2*) of the human immunodeficiency viruses was being described by amino acid homologies. There

<sup>210</sup> See Chapter 29 *Discovery of HIV and Development of Screening Tests* at paragraph 29.4, footnote 6 for Professor Lever's view, based on further study, that HIV does not properly belong to the lentivirus genus.

was a long discussion on the clinical safety of immune globulins. Genetic analysis had now begun to dominate scientific thought: there was little or no scope for doubt about the cause of AIDS transmission more generally.<sup>211</sup>

### *The modern view*

**11.176** As discussed in Chapter 8, *Knowledge of HIV/AIDS Now*, the modern view of the aetiology of AIDS is heavily influenced by the findings of geneticists of some fundamental characteristics of the virus. Before the identification of the first retroviruses, first in other animals and then in humans (in the form of HTLV-I), it was believed that there was a single direction of flow of information in the replication of pathogens, from DNA to RNA to protein. Then retroviruses were identified. When viruses in this group were first identified, it appeared that the genetic material within the virus particle was made of RNA but it was eventually established that when the virus entered a cell the RNA was converted backwards into DNA material. That DNA material was then inserted into the DNA of the cell so that it looked like part of the cell's own DNA. Because of that apparent reversal of the flow of genetic information from RNA back to DNA, this family of viruses came to be called retroviruses. This family includes Hepatitis B, which also goes through a DNA intermediate. The term 'retro' comes from that original observation that the flow of genetic information went backwards. When cell replication begins, the flow of genetic information goes in the normal direction again because that DNA is made into an RNA copy and into protein which, in addition to normal cell products, also produces the virus, since the instructions are now encoded into the cellular DNA.<sup>212</sup>

**11.177** Professor Lever emphasised some of the common characteristics of the natural history of virus infection generally.<sup>213</sup> On general principle, the more often a person is exposed to virus infection or the bigger the 'dose' of viral particles, the more likely is the chance of infection.<sup>214</sup> More often than not, the patient mounts an appropriate immune response, clears the infection and is then immune from further infection by the same agent: the immune system remembers the infection and prevents recurrence. Mumps and rubella were taken as typical examples. At the start of the AIDS epidemic, it was known that in the case of some chronic infections, such as Hepatitis B, while some people were relatively poor at clearing the virus and a proportion of these became chronic carriers, the majority of healthy individuals did appear to be able to clear it and develop immunity from re-infection. This experience informed the common notion at the time that exposure to infectious agents gave a level of protection against further infection by the same virus. A perception had arisen that, having been exposed to a virus, the individual would not be harmed by being exposed to the same virus again because either the immune system would have developed sufficient immunity to protect the individual completely or it would somehow help to suppress the second exposure. However, almost without precedent at the time, it was to emerge that, in the case of HIV, prior exposure to the virus gave no protection against infection on further exposure.<sup>215</sup>

**11.178** As already noted, a similar discovery was later to emerge in the case of Hepatitis C. Immunity from further infection does not follow from clearance of infection with the virus.

<sup>211</sup> See Chapter 10 *Knowledge of the Geographic Spread and Prevalence of HIV/AIDS 2* at paragraphs 10.118–10.120 for an illustration of the application of genetic analysis in tracing the source(s) of infection of batch 023110090, for example.

## Discussion

**11.179** With the identification of AIDS in 1981, scientists and clinicians were confronted by a phenomenon, unique at that time in modern medicine: a disease of no known aetiology that was rapidly progressive and fatal. Initially it appeared to affect a small set of vulnerable individuals whose known behavioural characteristics suggested that the scope of the disease was limited to promiscuous male homosexuals. Evidence undermining that hypothesis was soon to emerge in 1982 but alternative hypotheses as to the cause of AIDS, especially alternatives that depended on an agent of transmission, could not be proved in the absence of evidence that such an agent existed. There was a period of intense research and a virus was found that provided the answer to general, though not universal, satisfaction. It is important to stress that proof of a viral aetiology was provided, in France and the USA, within about three years of the first reported cases, and within two years of the initial evidence supporting the transmissible agent hypothesis. This was a remarkably short period.

**11.180** Success was achieved against the background of controversy. The CDC, and Dr Evatt in particular, became convinced by about July 1982, by evidence of infection in haemophilia patients, that AIDS was a blood-borne disease, though there was no direct proof. As late as 4 January 1983, at the advisory committee meeting convened in Atlanta, there was a hostile reaction to Dr Evatt's arguments.<sup>216</sup> By the summer of 1983 there was continuing doubt in some segments of the haemophilia community, the blood banking industry, physicians and the FDA in the USA that AIDS was a blood-borne infection.<sup>217</sup>

**11.181** The publication in *Science* by the Institut Pasteur of the isolation of LAV did not resolve the controversy. It would be February 1984 before those results were presented to the CDC. The position changed with the publication of Dr Gallo's findings in April. However, that was dramatic progress from a state of total ignorance of the disease and its viral aetiology to convincing proof.

**11.182** This chapter has set out, at some length, the evolving discussion of the alternatives, especially in the case of haemophilia patients, as the position would have been understood to clinicians and as discussed in professional literature as well as in evidence to the Inquiry.

**11.183** The pace of development of knowledge of the disease, and the concentrated effort made within a very short time to deal with the problem presented by its sudden and unanticipated appearance are particularly remarkable. As will appear from Chapter 29 *The Discovery of HIV and the Development of Screening Tests*, the public debate among haemophilia clinicians and others referred to in this chapter was for the most part irrelevant to that progress. The scientists responsible for cutting edge research and technological progress were convinced at an early stage of the viral aetiology of AIDS and were largely untouched by the debate. In contrast, doubt concerning a viral or otherwise infectious aetiology was strongest amongst haemophilia clinicians, some of whom sought other explanations (notably 'immune overload') for as long as such explanations remained tenable. This debate was fundamental to clinical practice in the treatment of haemophilia and other coagulation defect patients.

## CHAPTER 12

### HIV/AIDS: RESPONSE AND CLINICAL PRACTICE

#### Introduction

**12.1** As knowledge developed in the USA, in the UK generally, and in Scotland in particular, first of AIDS and then of HIV, it inevitably had an impact on clinical practice. Chapters 9–11 set out those developments at length and are not repeated in detail in this chapter, except where necessary to provide context. Rather, this chapter of the Report discusses aspects of the response to HIV/AIDS by haemophilia clinicians over the early and middle years of the 1980s. In particular, the question to be addressed is whether clinicians in Scotland should have adapted their treatment regimes sooner than they did, in response to the threat of AIDS.

**12.2** That is a difficult issue and the context in which it has to be addressed must take account of what was happening in the rest of the UK. Scottish haemophilia clinicians did not function in isolation from their counterparts in England and Wales. The constituencies represented by the United Kingdom Haemophilia Centre Directors' Organisation (UKHCDO) and, at that time, the Haemophilia Society, were UK-wide. It is likely that views expressed and attitudes communicated in their publications would have had an impact in Scotland, as information about AIDS was nationally disseminated. In discussing when Scottish practitioners should have reconsidered haemophilia therapy generally and whether such changes in clinical practice as did occur should have been made earlier, it is therefore appropriate to have regard to what was happening in the rest of the UK.

**12.3** Although it is necessary to take into account developing views throughout the UK, as these formed an important part of the background for clinicians as they responded to the emerging threat of AIDS, it is also important to bear in mind the degree of independence in clinical matters afforded to individual Regional Transfusion Directors (RTDs) and Haemophilia Directors at the time. As noted in Chapter 21, *Haemophilia Therapy – Use of Blood Products 1985–1987*, individual RTDs of the SNBTS and Haemophilia Directors in the UK, asserted and were accorded a high degree of autonomy in their practices.<sup>1</sup> This was not limited to clinical independence at the point of delivery of care to the patient; so far as is relevant to this chapter, it also included the selection and use of therapeutic products generally. There were significant regional differences in practice throughout the UK. In Scotland, the variations in clinical practice are illustrated by the analytical tables and figures in Chapter 21, *Haemophilia Therapy – Use of Blood Products*. These are discussed in more detail below.

**12.4** The question that naturally and understandably arises from haemophilia patients who acquired HIV infection, is why they were prescribed large-pool factor concentrates when there was, as is now known, a disproportionate risk of transmission of HIV by those products as compared to treatments such as cryoprecipitate and fresh frozen plasma which might, for some patients, have represented appropriate alternative therapies.<sup>2</sup> The question cannot be

<sup>1</sup> See also Professor Ludlam – Day 18, page 102. Closer co-operation developed from the mid-1980s.

<sup>2</sup> Cryoprecipitate was responsible for the transmission of HIV in some countries although, so far as is known to the Inquiry, not in the UK. Belgium, which used mainly cryoprecipitate from local donations for the treatment of haemophilia, had a 7% rate of HIV infection in haemophilia patients. See: Hagen, PJ *Blood Transfusion in Europe: a 'white paper'*, Council of Europe: 1994, and Dr Winter – Day 16, page 127. Professor Leikola noted that Finland used 'small-pool' cryoprecipitate during the relevant period due to a lack of locally produced concentrates and that only 2 patients were infected with HIV by that means. [PEN.013.1395] at 1397–8.

answered in a simple and straightforward way for all of Scotland, much less for the UK as a whole. Implicit in the question is an assumption that clinicians were, at the material time, in possession of sufficient evidence of disproportionate risk in large-pool concentrates such that they should have adapted treatment regimes sooner than they did. That assumption may not be valid, however, and it is necessary to distinguish the existence of risk in an absolute sense from knowledge of risk sufficient to instruct a reasoned decision on therapy. In addition, the therapeutic options available to clinicians differed across the country; even within a given region, different options were available to individual patients.

**Key issues: the debate on the aetiology of AIDS; advances in haemophilia care; and faith in the safety of the UK blood supply**

**12.5** The question is complicated by a number of fundamental issues addressed in this chapter. In the first place, for much of the period before HTLV-III/HIV was identified as the infective agent causing the immune deficiencies in patients who progressed to AIDS, there were competing theories supported by bodies of influential experts on both sides of the Atlantic. The full significance of the discovery in France of LAV<sup>3</sup> in May 1983 was not widely understood and those findings were resisted by many, particularly in the USA. Medical science did not resolve the fundamental question of the cause of AIDS, to the satisfaction of the majority of experts, until the spring of 1984. Even after the seminal publication in *Science* announcing the discovery of HTLV-III, some comments continued to be published challenging the findings that AIDS was spread by means of a virus present in blood. The history is set out in detail in Chapter 11, *HIV/AIDS Aetiology*, although, for the purposes of this chapter, a few key dates are important in discussing the timing of developments in clinical practice. Secondly, there was an acknowledgement that the development of large-pool concentrates had transformed the lives of haemophilia patients. Under such circumstances, many haemophilia clinicians, and others, appear to have been reluctant to accept evidence that those therapeutic materials might have transmitted infection to their patients. Thirdly, and perhaps linked to the last point, there was a long-held and strongly felt confidence in the safety of the UK blood supply. Early reports of AIDS infection were limited to the USA and, for those who might have been prepared to entertain the idea that AIDS was caused by a blood-borne infective agent, this confidence in the relative safety of NHS blood products may also have influenced thinking on the appropriate response to AIDS.

***Irreconcilable views on the aetiology of AIDS***

**12.6** Early reports of what came to be known as HIV/AIDS infection first emerged in the USA in 1981 and the initial debate on the disease was heavily influenced by the fact that most of the earliest reports dealt exclusively with homosexual men. The major pathological features of AIDS were very profound immunosuppression (with characteristic suppression of the ratio of helper to suppressor cells) and the development of certain otherwise rare diseases such as *Pneumocystis carinii* pneumonia (PCP) and the vascular cancer, Kaposi's sarcoma (KS). Starting in 1982 similar, if less marked, immune phenomena were identified in homosexual men who appeared healthy and, in particular, did not have overt disease characteristics of AIDS.<sup>4</sup> Also in 1982, immigrants to the USA from Haiti and intravenous

<sup>3</sup> Lymphadenopathy-Associated Virus, the name given by French researchers to the AIDS-causing virus, subsequently found to be identical to HTLV-III, the discovery of which was announced by Robert Gallo in April 1984. The virus was ultimately renamed HIV. See Chapter 11, *HIV/AIDS Aetiology*.

<sup>4</sup> Gold et al, 'Acquired Immunodeficiency Syndrome: Infection and Neoplasia in Homosexual Men and Intravenous Drug Addicts', *Proceedings of the Second International Symposium on Infections in the Immunocompromised Host*, 1983, Academic Press, London [LIT.001.3668]

drug users (IVDUs) began to present with similar immune dysfunction and, occasionally, overt disease.<sup>5</sup> In July 1982, 'opportunistic infections' characteristic of AIDS were found in three US haemophilia patients who had received frequent administration of Factor VIII,<sup>6</sup> and further reports followed.

**12.7** Irreconcilable views on the aetiology of AIDS emerged in 1982 and were expressed clearly at a workshop in Atlanta on 4 January 1983.<sup>7</sup> The 'transmissible agent' theory was supported by the American Centers for Disease Control (CDC), whose spokesman was Dr Bruce Evatt. That theory of AIDS transmission postulated that a blood-borne virus was responsible for the observed cases (including those in haemophilia patients). By contrast, the 'antigen overload' theory was supported by a body of haemophilia clinicians, whose most prominent spokesman was Dr Louis Aledort, a respected haematologist and Director of the Haemophilia Center in New York. That theory considered exposure to foreign antigens in concentrates to have caused a high degree of antigenic stimulation that wore out haemophilia patients' immune systems. Both views were strongly held and forcefully argued.

**12.8** At various points in 1983 the competing theories were supported or criticised in published papers and at conferences. At this time in Scotland, Professor Christopher Ludlam (Edinburgh Haemophilia Centre) and Professor Charles Forbes (Glasgow Haemophilia Centre) conducted studies into the phenomena of immune irregularities in haemophilia patients. Of these, Professor Ludlam's studies led more positively to the view, published in *The Lancet* on 28 May 1983, that the immune changes identified in his patients resulted from infusion of 'foreign' proteins in the therapeutic products administered to them, or a ubiquitous virus, rather than a specific AIDS virus in Factor VIII concentrates: the antigen overload theory.<sup>8</sup> These studies are referred to in more detail, in a specifically Scottish context, below at paragraphs 12.111–12.119.

**12.9** By the time of the meeting of the World Federation of Hemophilia in June 1983, Françoise Barré-Sinoussi and Luc Montagnier of the Institut Pasteur, Paris, had published the results of research suggesting that they had identified an infectious agent, which they termed LAV.<sup>9</sup> That was, however, not generally accepted as persuasive (especially in the USA) until 23 April 1984, when Dr Robert Gallo and his team announced the discovery of HTLV-III.<sup>10</sup> Later research was to demonstrate that LAV and HTLV-III were, in fact, the same

<sup>5</sup> Masur et al, 'An Outbreak of Community-Acquired Pneumocystis Carinii Pneumonia', *New England Journal of Medicine*, 305(14): 1431–1438 [LIT.001.0771]; 'Opportunistic Infections and Kaposi's Sarcoma among Haitians in the United States' *MMWR*, July 09, 1982;31:353-4, 360-1 [LIT.001.0562]

<sup>6</sup> 'Pneumocystis carinii Pneumonia among Persons with Hemophilia A', *MMWR*, July 16, 1982; 31 [SGH.008.5097]. It appears that the earliest case of AIDS in a haemophilia patient may have been identified in October 1981, although it was not reported until February 1983. Discussions between Dr Oscar Ratnoff, Cleveland, Ohio, and Professor Charles Forbes, Glasgow, at the end of 1981 were probably related to this case, undoubtedly extremely unusual and puzzling at the time. See Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*, paragraph 9.22.

<sup>10</sup> Gallo et al, 'Frequent detection and isolation of cytopathic retroviruses (HTLV III) from patients with AIDS and at risk for AIDS', *Science* 1984; 224:500–503 [LIT.001.3769]; Popovic et al, 'Detection, Isolation, and Continuous Production of Cytopathic Retroviruses (HTLV-III) from Patients with AIDS and Pre-AIDS', *Science* 1984, 224. (reprint) [SNB0049457] See also Chapter 29, *Discovery*, paragraphs 29.5–29.10.

virus, later named HIV.<sup>11</sup> The position until April 1984 was summed up by Professor Lever, Professor of Infectious Diseases at Addenbrooke's Hospital, Cambridge:

Up until that time I think it's a gradation. There was gradual acceptance that it couldn't just be put down to immunological-based theories and that the epidemiology looked more and more like an infectious agent.<sup>12</sup>

**12.10** It appears that Dr Mark Winter, Consultant Haematologist at Kent and Canterbury Hospital from 1983, accepted the infective agent theory at a relatively early date<sup>13</sup> but it is not clear that, by April 1984, the 'gradation' Professor Lever described encompassed all interested parties. In this context, it is of interest to note that, in a paper detailing testing for HTLV-III that was underway in the second half of 1984, the linking of antibody-positivity to AIDS was still presented as a hypothesis, albeit one which 'strongly implicated' a transmissible agent.<sup>14</sup> Even after that point, some commentators continued to publish articles sceptical of the claim that AIDS was caused by a transmissible virus<sup>15</sup> although, increasingly throughout the period and certainly after April 1984, that scepticism appears to have involved finding alternative explanations for the considerable accumulating evidence supporting the transmissible agent theory. Given the gradual progress of developing knowledge, however, and the fundamental differences of opinion that prevailed throughout 1983 and into 1984, it was highly unlikely that a view common to all or most haemophilia clinicians would have emerged before April 1984 that accepted the infectious agent theory. It is clear from the evidence available to the Inquiry that the infectious agent theory did not prevail until at least then, with some continuing to defend alternative hypotheses for some months after that date. It also appears clear from the evidence that, throughout the period of uncertainty, some haemophilia clinicians at least found their assessment of the risk associated with blood products to some extent confounded by an appreciation of the significant benefits large-pool concentrates used in coagulation disorder therapy had brought to their patients.

### *The significance of advances in haemophilia care*

**12.11** Before it was recognised that the use of factor concentrates might present a risk of immune deficiencies in coagulation disorder patients, whether caused by an infective agent or by antigen overload, the development of factor products (including cryoprecipitate but particularly large-pool concentrates) had brought about a major advance in healthcare. The improvement in life expectancy, the reduction in morbidity and improvements in the quality of life of haemophilia patients achieved were little short of spectacular.<sup>16</sup>

**12.12** Therapy for Haemophilia A and Haemophilia B in particular had revolutionised the lives of patients. At a meeting on the Infectious Hazards of Blood Products arranged by the National Institute for Biological Standards and Control (NIBSC) on 9 February 1984, Dr Duncan Thomas<sup>17</sup> noted the improvement in life expectancy which had resulted from the use of concentrates, from 37 years in 1962 to almost normal in 1984.<sup>18</sup>

<sup>11</sup> Cheingsong-Popov et al, 'Prevalence of antibody to human T-lymphotropic virus type III in AIDS and AIDS-risk patients in Britain', *The Lancet*, 1 September 1984; 477-480

<sup>12</sup> Day 26, page 41

<sup>13</sup> See paragraph 12.51 below

<sup>14</sup> Cheingsong-Popov et al, 'Prevalence of antibody to human T-lymphotropic virus type III in AIDS and AIDS-risk patients in Britain', *The Lancet*, 1984; 477-480 [LIT.001.0417] The paper noted that '[t]he likelihood of ... AIDS being caused by an infectious agent has been apparent for some years.' It noted new evidence implicating LAV/HTLV-III but still, at that point, was not definitive in its statements: 'Even if HTLV-III is causally related to AIDS ... as is strongly suggested by the evidence.'

<sup>15</sup> See Chapter 11, *HIV/AIDS Aetiology*

<sup>16</sup> See Chapter 21, *Haemophilia Therapy – Use of Blood Products*

<sup>17</sup> Head of Haematology at the NIBSC

<sup>18</sup> Minutes of the NIBSC meeting on the infectious hazards of blood products, 9 February 1984 [SNB.004.8628]

**12.13** A significant factor in these improvements was the development of ‘home therapy’ treatment programmes. Prior to the introduction of factor concentrates, haemophilia patients who experienced bleeds would attend hospital for treatment, typically with cryoprecipitate. It was impractical for most patients to keep stocks of cryoprecipitate at home for self-administration as the packs required to be stored in large quantities in deep freezers<sup>19</sup> and, compared with factor concentrates, were difficult to prepare, requiring to be reconstituted from the frozen state in a water bath at 37°C in a clean, or ideally sterile, environment.<sup>20</sup> In addition, the potency of cryoprecipitate could not be known until the point of administration and the product was frequently associated with significant side-effects, some of which could require hospital care.<sup>21</sup> By contrast, factor concentrates could be stored in a refrigerator (requiring only to be stored at 4°C), potency was more uniform and, after training, could be more easily prepared and administered by patients (or, in the case of younger children, their parents). Side-effects, at the point of administration, were less common. Patients no longer needed to attend hospital following a bleed, an experience Dr Winter described as ‘harrowing’ and ‘a pretty dreadful experience’.<sup>22</sup> A textbook on paediatric haematology written by Dr Michael Willoughby, at the time Director of the Haemophilia Centre at The Royal Hospital for Sick Children, Yorkhill, Glasgow (Yorkhill), and published in 1977 set out the advantages of factor concentrates as compared to cryoprecipitate and noted that ‘home treatment is highly efficacious in reducing the morbidity of haemophilia and improving the quality of life’.<sup>23</sup>

**12.14** Upon taking up the post of Director of the Edinburgh Haemophilia Centre in 1980, Professor Ludlam began almost immediately to radically expand the home therapy programme, using concentrates, in that area. As discussed below, his predecessor, Dr Howard Davies, had been somewhat circumspect in relation to the use of concentrates. Although they were not infrequently used while he was Director, Dr Davies was concerned about the risks associated with large-pool products. As a result, at the beginning of 1980 only six of a total of 187 haemophilia patients registered at the Centre were established on home therapy. Professor Ludlam said he was ‘continuingly being asked’ to expand the programme for which there was ‘a lot of enthusiasm’.<sup>24</sup> By 1989, this number had grown to 47. He considered cryoprecipitate inappropriate for home therapy and was ‘not prepared to take the risk’ he saw in placing patients on home therapy with cryoprecipitate.<sup>25</sup> Dr Boulton, who began working in Edinburgh around the same time, agreed.<sup>26</sup> Professor Ludlam may have been constrained in his efforts to expand the home treatment programme due to his stated preference for locally-sourced factor concentrates.<sup>27</sup> The drive towards increasing the number of patients on home therapy led him to impress upon the SNBTS his desire to have more NHS Factor VIII concentrate.<sup>28</sup>

<sup>19</sup> As noted in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, paragraph 21.73, footnote 51, various sources provide different temperatures at which cryoprecipitate required to be frozen, ranging from -70°C to -18°C and it has not been possible to specify with accuracy the storage requirements at the material time. As noted in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, compared to concentrates, cryoprecipitate had to be administered in very large quantities. Professor Ludlam agreed that there was ‘quite a large storage problem’. Day 18, page 37

<sup>20</sup> Dr Winter – Day 15, page 79; Professor Ludlam – Day 18, pages 34–35

<sup>21</sup> Dr Winter – Day 15, page 79; Professor Ludlam – Day 18, pages 37–38

<sup>22</sup> Day 15, page 80

<sup>23</sup> Willoughby, MLN. *Paediatric Haematology*, 1977: Churchill Livingstone, Edinburgh, London, New York p321 [PEN.016.1062] at 1068

<sup>24</sup> Day 18, page 89

<sup>25</sup> *Ibid* page 72. Professor Ludlam also noted that, almost certainly due to the volume of cryoprecipitate required to encourage normal clotting, over a course of treatment with cryoprecipitate patients ‘not infrequently ... became jaundiced’ indicating hepatitis infection. Day 18, page 39

<sup>26</sup> Day 24, pages 13–16

<sup>27</sup> ‘My clinical decision was to delay home treatment, rather than use commercial concentrates because of the different virological spectrum of the donors.’ Day 19, page 39

<sup>28</sup> See Chapter 21, *Haemophilia – Use of Blood Products*, paragraph 21.109

**12.15** There was an obvious major benefit derived from treatment, especially with large-pool concentrates as they were developed from the early 1970s.<sup>29</sup> There was a reduction in the number of school or work days lost; patients could travel more easily, whether on holiday or for business; and patients were spared frequent ‘time-consuming and psychologically undesirable’ visits to hospital.<sup>30</sup> Professor Forbes agreed that home therapy was ‘a very popular move’, describing the relatively short period between the development of home therapy programmes and the emergence of non-A, non-B Hepatitis and AIDS as ‘the golden age’ in haemophilia care.<sup>31</sup> As discussed in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, paragraphs 21.95–21.100, the development of home treatment programmes had a significant effect on the demand for factor concentrates and production of concentrates increased accordingly to meet demand. In the absence of an alternative of proven efficacy, for many clinicians ceasing to use concentrates threatened patients’ quality of life, health and even their lives.

**12.16** Professor Forbes said:

For a long time after the initial cases of AIDS was [sic] reported there was great debate about the best way of treating bleeding. It was certainly not possible to stop the use of concentrate as bleeding would have resulted in death and the general reaction of most Haemophilia Directors at that time was to continuing [sic] to treat the bleeding with concentrate.<sup>32</sup>

**12.17** In oral evidence to the Inquiry, Professor Forbes said that he thought that the 1983 decision to continue treatment with concentrates was correct.<sup>33</sup> Similar views persisted into 1984. Professor Arthur Bloom, Cardiff Haemophilia Centre, took up the theme in an article in *The Lancet* dated 30 June 1984. He commented:

In view of the immense benefits that haemophiliacs have derived from treatment physicians are naturally reluctant to abandon these agents, with their hypothetical dangers, in the absence of alternative concentrates which have been proven safer. This attitude may change as information accrues, and haemophilia treatment needs to be monitored world-wide.<sup>34</sup>

**12.18** Against this background, it is not surprising that there was a range of strongly held views. The approach of Dr Aledort at the workshop in Atlanta on 4 January 1983 reflected the position held at one extreme of that range. There were clinicians who demanded full scientific proof of an infective agent as a condition of changing from established factor concentrate therapy.<sup>35</sup>

<sup>29</sup> Dr Winter – Day 16, pages 13–14

<sup>30</sup> Willoughby, MLN. *Paediatric Haematology*, 1977: Churchill Livingstone, Edinburgh, London, New York p321 [PEN.016.1062] at 1068

<sup>31</sup> Professor Forbes – Day 17, page 58. See also Dr Winter – Day 15, page 73 – who referred to this period as the ‘golden interval’ in haemophilia care.

<sup>32</sup> Statement of Professor Forbes [PEN.015.0254] at 0257

<sup>33</sup> Professor Forbes – Day 17, pages 97–98

<sup>34</sup> Bloom, ‘Acquired Immunodeficiency Syndrome and other Possible Immunological Disorders in European Haemophiliacs’, *The Lancet*, 30 June 1984; 1452–1455 [LIT.001.0409] at 0412

<sup>35</sup> See Chapter 11, *HIV/AIDS Aetiology*, paragraphs 11.28–11.35. The demand was that the proponents of the transmissible agent theory should ‘[s]ubject [the theory] to Koch’s postulates’, a well-established protocol for demonstrating the transmission of bacterial infection.

### *Faith in the safety of the UK blood supply*

**12.19** Further to the significance of advances in haemophilia care, there was faith in blood factor products, both cryoprecipitate and concentrates, produced by UK public sector facilities that strongly influenced many (but not all) practitioners throughout the UK. From the beginning of the AIDS era until 1984, this faith had at its roots a belief that, if AIDS was indeed caused by an infective agent, it had not entered the blood donor population in the UK generally and in Scotland in particular. Accordingly, for those who subscribed to the infective agent hypothesis, it was thought that Factor VIII produced in the UK was unlikely to transmit the postulated AIDS virus. Those who acknowledged that there was a risk thought it was minor. It was deeply ingrained in the psyche of haemophilia clinicians and patients, that donated blood of UK origin was much more likely to be free of viruses than blood from the USA.

**12.20** The situation in Edinburgh illustrates this point particularly well. Professor Ludlam's predecessor as Director of the Edinburgh Haemophilia Centre, Dr Howard Davies, made almost exclusive use of locally-produced therapeutic materials. Professor Ludlam stated that Dr Davies avoided the use of imported materials as a matter of policy, believing those derived from Scottish donors would be safer. Dr Davies' argument in preference of locally sourced materials centred on the risks associated with hepatitis viruses, but appears to have had a more general basis: both Professor Ludlam and Dr McClelland stated that Dr Davies was reluctant to potentially introduce 'novel' viruses to the local population. Dr Brian McClelland,<sup>36</sup> who worked with Dr Davies early in his (Dr McClelland's) career, said that Dr Davies' policy struck him as 'eminently sensible'. In relation to imported products, he thought the policy was grounded in 'elementary biology' and that 'the further afield the blood came from, there was a certainly incalculable but reasonable grounds to expect that something new and different and unfamiliar to the indigenous population might be in that blood'.<sup>37</sup> Dr Davies also tended to avoid large-pool concentrates, preferring, where possible, to use cryoprecipitate in the belief that large pools of donations were more likely to contain transmissible viruses, whatever their source. As noted above, when Professor Ludlam succeeded Dr Davies, he quickly reversed this part of Dr Davies' policy and moved as many patients as he could to home therapy with concentrates. He continued, however, to prefer locally produced products, believing that the general population of Scotland was at the time relatively 'stable' and that the risks associated with the local donor pool were 'small'.<sup>38</sup> Dr Davies' thinking on this was, he said, for its time, 'very sensible ... [o]therwise I wouldn't have continued it'.<sup>39</sup>

**12.21** Professor Ludlam's faith in the relative safety of the UK blood supply is perhaps most clearly demonstrated in relation to a policy he adopted towards patients under his care who might require to travel. A national system in place from the 1970s ensured that all UK haemophilia patients were given a card stating their condition, its severity and details of their local Haemophilia Centre. Professor Ludlam added to this a printed statement requesting that, if a patient was treated elsewhere than their local Centre, either cryoprecipitate or NHS factor concentrates be used in preference to commercial concentrates. He stated that he had provided his patients with the additional statement

<sup>36</sup> Director of the Edinburgh and East of Scotland Blood Transfusion Service, 1979–2001

<sup>37</sup> Day 21, page 153

<sup>38</sup> Day 35, pages 21–22

<sup>39</sup> Day 19, page 126

specifically so that, if they were to require treatment away from home – and particularly in England or Wales where there was considerably less NHS material available – his patients would not be exposed to commercial concentrates.<sup>40</sup>

**12.22** Not all clinicians favoured this approach. Dr Willoughby, until he was succeeded by Professor Ian Hann at Yorkhill, had ‘what appeared to be a preference for commercially (as opposed to NHS-produced) products’.<sup>41</sup> Although, as noted above, Dr Willoughby agreed that home treatment programmes were of proven efficacy, he believed commercial concentrate was a better product for that purpose, being of higher purity, resulting in fewer adverse reactions and being easier to prepare.<sup>42</sup> At least part of his approach, however, appears also to have been based on the availability of locally produced materials: in a discussion with Professor Hann, Dr Willoughby expressed disillusionment with the health service throughout the UK generally and, in particular, that he felt let down with regard to supplies.<sup>43</sup>

**12.23** As noted below in discussion of product selection at Scottish centres, Professor Hann immediately reversed this policy upon taking up the post of Haemophilia Director at Yorkhill. Professor Hann believed that, as well as being cheaper, locally produced products would be safer because the donor pool was better. He had taken into account potential problems with this approach, including availability, but for him, ‘the lower risk of infectivity was ... paramount’.<sup>44</sup> Professor Hann did not, however, criticise Dr Willoughby’s preference. It appears clear that Dr Willoughby had exercised his clinical judgement and that he reached his conclusions for what he regarded as good reasons. Dr Willoughby had not had to face the emerging problems of non-A, non-B Hepatitis/Hepatitis C or HIV/AIDS, however, and another part of the explanation for his preference and practice may have been a belief that what he perceived as the greatest risk to haemophilia patients, Hepatitis B, was reducing and that avoiding large-pool concentrates more effectively reduced that risk, than preferring large but local donor pools.<sup>45</sup>

**12.24** The selection of therapeutic materials in the three other Scottish centres (Aberdeen, Dundee and Inverness) point clearly towards a preference for NHS products. As will be seen below in discussion of the actual products administered, use of imported commercial concentrates was very infrequent throughout the material time at Aberdeen and Dundee, while Inverness used no imported products from 1974 onwards. Practice at these centres appears to have closely followed international, government and SNBTS guidance and policy that haemophilia treatment should be on a self-sufficient basis using domestically sourced products, other than in exceptional cases.

**12.25** The existence of HTLV-III/HIV infection in haemophilia patients in the UK emerged with a dreadful suddenness, however, after the publication of the seminal article in *The*

<sup>40</sup> Day 18, pages 68–69; Day 19, pages 117–118

<sup>41</sup> Professor Hann’s Witness Statement [PEN.015.0035] at 0037; Day 21, page 27

<sup>42</sup> Day 21, page 28. Dr Pettigrew, who worked with Dr Willoughby, agreed that, at that time, NHS Factor VIII could be ‘difficult to work with’ and that the commercial alternatives were ‘much more user-friendly’. She noted that the parents of haemophilia patients at Yorkhill also tended to favour commercial products for the same reasons. Day 20, pages 17–18. Professor Ludlam also agreed that early concentrates could be difficult to ‘solubilise’, although he thought this common to both commercial and NHS concentrates. Day 18, page 43

<sup>44</sup> Day 31, page 81

<sup>45</sup> Day 21, page 29; Day 31, pages 80–81. Professor Ludlam agreed that Dr Willoughby was ‘a very good, enthusiastic paediatric haematologist’ and did not criticise his approach to product selection at Yorkhill. Day 18, pages 101–102

*Lancet* on 1 September 1984 by Dr Rachanee Cheingsong-Popov and others.<sup>46</sup> The article presented strong evidence supporting the infectious agent hypothesis and gave the results of 2000 HTLV-III tests conducted in the UK. It commented that there had previously been reported only limited studies of antibody prevalence in groups at risk for AIDS, but that those studies had shown a moderately high seropositivity amongst at-risk populations such as apparently symptom-free homosexual men, haemophilia patients and IVDUs. Antibodies to HTLV-III were found in 34% of haemophilia patients studied, but the article advised caution in interpreting the results. There was perceived at that time to be a relatively low risk of acquiring HTLV-III or AIDS from blood transfusion in the UK, which was said to be regarded as a 'low-risk country'.

**12.26** In retrospect, it is difficult to understand the confidence in UK blood in its most extreme form, at least among those who accepted the transmissible agent theory in the debate over the aetiology of AIDS. By 1980 international tourism was well established, both in foreign holidays for UK residents and in holidays in the UK for foreign residents. The interchange across borders of individuals with an interest in activities that exposed them to a high risk of HIV infection, whether the risk was associated with intravenous drug use or promiscuous male homosexual activity, was known from the earliest cases of AIDS in the UK to be associated with travel.<sup>47</sup> An editorial in *The Lancet* of 22 December 1984 commented on an article by Dr Mads Melbye and others in the same edition, which noted that anti-HTLV-III seropositivity in Danish homosexual men was most strongly correlated with travel to the USA and especially New York City<sup>48</sup> and noted that, of Scottish patients studied in Glasgow, of those treated with domestically sourced product only those who had travelled abroad were HTLV-III antibody positive. It observed that contamination of local blood products with HTLV-III must only be a matter of time, effectively recognising the reality that had already emerged.<sup>49</sup>

### ***Clinical practice in the United States of America; in England and Wales; and in Scotland***

**12.27** The chronology of the emergence of AIDS has been dealt with in detail elsewhere (see Chapters 9–10). In examining the clinical response to these developments, it is appropriate in the first instance to have regard to attitudes and actions in the USA, where the first AIDS cases were identified and where it was quickly recognised that AIDS was potentially a major public health issue. The UK presented a very different picture, however, and within the UK there were significant differences in treatment regimes for haemophilia therapy as between England and Wales on the one hand and Scotland on the other. Chief amongst these was the availability of therapeutic materials derived from UK donors: in England and Wales, these accounted for only a small proportion of the required products and the importation of commercial products was correspondingly high. By contrast, Scotland was increasingly able to produce a much greater proportion of therapeutic materials from domestically sourced blood and the importation of commercial products was considerably lower. After the discussion of the clinical response in the USA, therefore, there follows discussion of opinions and reactions in England and Wales before the clinical response particular to Scotland is considered.

## Clinical response to the emergence of AIDS: The United States of America

### *Initial response*

**12.28** The initial response to the emergence of AIDS in the USA<sup>50</sup> was limited to advice on clinical practice in managing patients with diseases of the 'AIDS complex'. Clinicians were advised to treat the infections identified in patients suffering from the syndrome, so far as they were treatable. In addition to managing diagnosed disease, long-term prophylaxis for PCP was suggested as a possibility.<sup>51</sup> The focus was predominantly on patient care for those infected or suspected of having been infected with AIDS and those with AIDS-related conditions, rather than on preventative measures.

### *Haemophilia patients at risk*

**12.29** After it was reported in July 1982 that US haemophilia patients appeared to be at risk,<sup>52</sup> a wider approach was adopted generally in the USA. The US National Hemophilia Foundation (NHF) called for action to protect patients and, in collaboration with the CDC and the Food and Drug Administration (FDA), instituted a surveillance programme to determine patterns of AIDS transmission among haemophilia patients, with a view to establishing guidelines for treatment.<sup>53</sup>

**12.30** In response to the threat of AIDS some haemophilia clinicians in the USA, notably Dr Oscar Ratnoff of Cleveland, proposed that haemophilia patients should suspend the use of concentrates and revert to cryoprecipitate, prepared from pools of ten donors or fewer.<sup>54</sup> He was opposed by the pharmaceutical industry and by other haemophilia doctors. In December 1982, however, after a total of eight cases of haemophilia-associated AIDS had been reported, the first NHF directive was issued recommending that concentrates should not be introduced to those who had not previously been exposed to them, including newborn children and young children up to four years old; to newly diagnosed patients; and to patients with mild haemophilia. Cryoprecipitate and fresh frozen plasma were recommended for therapy in such patients instead.<sup>55</sup> This was an approach that appears to have been based, in those very early days of the AIDS epidemic, on caution rather than firm scientific proof of the relative risks of transmission by cryoprecipitate and concentrates.

**12.31** In January 1983, a further NHF directive recommended the use of Desmopressin (otherwise known as DDAVP, a synthetic replacement for the hormone vasopressin) for patients with mild and moderate haemophilia.<sup>56</sup> The directive also recommended delaying elective surgery. This reflected considerable suspicion that AIDS was due to a blood-borne agent but, at the time, the risk of haemophilia patients developing AIDS was perceived to be very low. The use of DDAVP, where possible, was perceived as a prudent, and conceivably safer, alternative to the use of concentrate.

<sup>50</sup> See Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1* for more detailed discussion.

**12.32** In US studies reported early in 1983, it was found that patients treated with cryoprecipitate did not develop impaired cell-mediated immunity.<sup>57</sup> As against the practical problems associated with a switch from concentrate therapy to cryoprecipitate, those studies appeared to suggest that cryoprecipitate exposed recipients to less risk of immune deficiencies than risks posed by concentrates.<sup>58</sup> Professor Ludlam noted, however, that it is now recognised that, largely due to variations in individuals' immune systems generally, immune changes such as those described were not necessarily a good reflection of HIV status.<sup>59</sup> As noted at paragraphs 12.114 and 12.118, it was to transpire that many of the haemophilia patients studied in Edinburgh and Glasgow, who showed changes in cell-mediated immunity, were not in fact HIV-positive at that time.<sup>60</sup> In addition, it was to transpire that in countries which used cryoprecipitate exclusively, HIV transmission still occurred, albeit to numbers of patients considerably lower than in those countries which used concentrates.<sup>61</sup>

**12.33** The preference for cryoprecipitate, as expressed by Dr Ratnoff, was repeated in an editorial in the *New England Journal of Medicine (NEJM)* of 13 January 1983 written by Dr Jane Desforges.<sup>62</sup> She commented that, in view of the results from the Lederman<sup>63</sup> and Menitove<sup>64</sup> studies reported in that edition (noted in the preceding paragraph), current modes of treatment would have to be scrutinised and suggested that, if cryoprecipitate use reduced the risk of haemophilia patients contracting AIDS, the current home treatment programme (using concentrate) needed to be revised. This was a more radical proposal than that contained in the NHF directive. She advised physicians involved in the care of haemophilia patients to be alert to the risk and wrote that, '[p]reventing the complications of the present treatment might have to take precedence over preventing the complications of haemophilia itself'. The withdrawal of factor concentrates was mooted, though it was acknowledged that there might not be enough evidence to demand such a radical change.<sup>65</sup> Professor Ludlam noted that Dr Desforges had accepted that the number of patients involved in her preliminary study was 'too small for definitive comparison of the risks of different modes of treatment' to be made.<sup>66</sup>

**12.34** These early responses related to haemophilia therapy suggested product selection in order to reduce risk in particularly vulnerable groups, or avoiding elective procedures so that blood product therapy would not be required. More generally, concentrate therapy

<sup>57</sup> Lederman et al 'Impaired Cell-Mediated Immunity in Patients with Classic Hemophilia', *New England Journal of Medicine*, 1983; 308: 79–83 [PEN.012.0263]; Menitove et al, 'T-Lymphocyte Subpopulations in Patients with Classic Haemophilia Treated with Cryoprecipitate and Lyophilized Concentrates', *New England Journal of Medicine*, 1983; 308: 83–86 [LIT.001.0031]. See also Chapter 11, *Aids Aetiology*, paragraphs 11.48–11.50

<sup>58</sup> See, however, paragraph 12.35 below: some clinicians thought that large quantities of cryoprecipitate were as likely to transmit infection as concentrates. In Chapter 2, *Patients at Risk*, paragraph 2.48, it is noted that cryoprecipitate is a high-volume product at the point of use and that, therefore, patients requiring frequent treatment were necessarily exposed to large numbers of donors. A patient experiencing 20 bleeds in a year might have been exposed to as many as 1600 units derived from up to the same number of donors.

<sup>59</sup> Day 18, page 122. See also Dr Kernoff's article for the Haemophilia Society publication, *The Bulletin* of 1983, discussed below. This contemporaneous article notes that the 'simplest' test for AIDS – measuring the ratio of T4 to T8 lymphocytes – 'is also the least meaningful' because 'low ratios are not unique to AIDS – similar results may be found in a variety of other circumstances. So the finding of a low ratio doesn't diagnose AIDS, and there's no evidence that it predicts it, either.' [PEN.016.0595] at 0606. In the UK, 'cell-mediated immunity', measured by T4/T8 ratios was considered insufficient for a diagnosis of AIDS (see Chapters 9–10).

<sup>66</sup> Professor Ludlam's Witness Statement [PEN.015.0445] at 0451

was considered unavoidable, save in the more radical proposals put forward by Drs Ratnoff and Desforges. Further proposals soon emerged in the USA but, as noted above, there was controversy over the infective agent hypothesis and possible solutions based on product selection were unlikely to be persuasive while the controversy remained unresolved.

**12.35** Realistically, however, the widespread use of cryoprecipitate as proposed by Dr Ratnoff and Dr Desforges had little prospect of success in the USA or elsewhere. Production facilities did not exist to provide the quantities of cryoprecipitate that would have been required, as indeed Dr Desforges had suggested in her article.<sup>67</sup> Other clinicians thought that because of the cumulative effect of infusing large quantities, cryoprecipitate would ultimately be as likely as concentrates to transmit disease.<sup>68</sup> Many clinicians, the blood products industry and, indeed, many patients strongly resisted switching from home therapy using concentrates to the use of cryoprecipitate, which would have ended the home therapy programme and resulted in haemophilia patients requiring to attend hospital when they experienced bleeds. Subsequently, in March 1985, Dr Ratnoff reported that of 91 patients under his care, only five had followed his advice and switched to cryoprecipitate therapy.<sup>69</sup> Professor Ludlam was not aware whether Dr Desforges had acted on her 'recommendation' and changed patients under her care from concentrate therapy to cryoprecipitate.<sup>70</sup>

### ***Statements on the prevention and control of AIDS***

**12.36** On 4 March 1983, the US Public Health Service noted that statements on the prevention and control of AIDS had been issued by the National Gay Task Force, the National Hemophilia Society, the American Red Cross, the American Association of Physicians for Human Rights and others. There was broad agreement that steps were required to reduce the potential risks but the organisations differed in the methods proposed to accomplish that goal. The Public Health Service made a number of general precautionary recommendations. So far as clinical practice was concerned, it recommended that physicians should adhere strictly to medical indications for transfusions and that autologous transfusions (whereby, in anticipation of planned surgical intervention, the patient gives their own blood in advance for use in the operation) should be encouraged. Manufacturers were encouraged to produce safer products.<sup>71</sup>

**12.37** A similar point was made in the March–April 1983 edition of the journal *Transfusion* which published a joint statement on AIDS related to blood transfusion.<sup>72</sup> The statement, which was dated 13 January 1983 and had been developed by the American Association of Blood Banks, the American Red Cross and the Council of Community Blood Centers, with both voluntary and government assistance, recommended that physicians should be educated further regarding the importance of balancing the decision to use each blood component against the risks of infection, be they well established or, like AIDS, under investigation.

<sup>72</sup> The Inquiry has not yet been able to trace this statement. See *Transfusion*, 1983; 23:87-88, 'Joint statement on acquired immune deficiency syndrome (AIDS) related to transfusion'

**12.38** The Medical and Scientific Advisory Council of the NHF began to produce a series of guidelines for the treatment of haemophilia patients, developed in response to the latest scientific and medical knowledge. Some of the guidelines of this period were reflected in the approaches of international bodies. For example, on 21 December 1982 the World Federation of Hemophilia issued the recommendation that:

[C]ryoprecipitate be used to treat patients in the following groups except where there is an overriding medical condition: new born infants and children under 4; newly identified patients never treated with factor VIII concentrate; and patients with clinically mild haemophilia who require infrequent treatment.<sup>73</sup>

**12.39** It was recommended that DDAVP should be used whenever possible in patients with mild or moderate Haemophilia A. These recommendations were a close parallel of the then current US Public Health Service recommendations.

**12.40** The wish of many haemophilia clinicians to maintain the status quo remained an important factor, however. In June 1983, Dr Aledort affirmed that his position on treatment was 'business as usual'. There was, in his view, no evidence that treatment with concentrates caused AIDS and no need to change therapy.<sup>74</sup>

### *The position in the United States of America at the end of 1983*

**12.41** By the end of 1983, a number of strategies had emerged in professional literature and in national agency directives in the USA:

- Physicians should adhere strictly to medical indications for transfusions.
- Physicians should be educated further regarding the importance of balancing the decision to use each blood component against the risks of infection, be they well established or potential.
- Autologous transfusions should be encouraged.
- Concentrates should not be introduced to those who have not previously been exposed to such treatment, including newborn children and young children up to four years old, newly diagnosed patients, and patients with mild haemophilia.
- According to one extreme of opinion, factor concentrates should be withdrawn.

**12.42** Two background factors appear to have been particularly important in influencing policy at the end of 1983:

- No transmissible aetiological agent of AIDS had been isolated or identified, to the satisfaction of leading authorities in the USA,<sup>75</sup> and there was no screening test to protect the blood supply.
- Strategies to reduce hepatitis infectivity in factor concentrates were in the course of development and it was presumed that, if the transmissible agent of AIDS were a virus, similar strategies could reduce the infectivity of other agents, including a possible AIDS agent.

<sup>73</sup> 'Medical and Scientific Advisory Council. AIDS: Implications Regarding Blood Product Use' National Hemophilia Foundation, 21 December 1982, New York [LOT.002.2661].

<sup>74</sup> Douglas Starr, *Blood*, Page 293 [LIT.001.2936] at 2963

<sup>75</sup> The virus had been isolated in France by Montagnier and others but this was not generally accepted at the time, particularly by US scientists and clinicians. See Chapter 11, *HIV/AIDS Aetiology*

## Clinical response to the emergence of AIDS: England and Wales

### *The aetiology of AIDS: transmissible agent or antigen overload?*

**12.43** As noted above, the emergence of AIDS, seen at the time as a genuinely new disease with no relevant history upon which to base decisions on appropriate action, gave rise to debate as to the aetiology of the condition. This debate itself – between those who believed that an infectious agent, probably a virus, was responsible for the observed clinical signs and symptoms in AIDS patients (the transmissible agent theory) and those who believed that those signs and symptoms were attributable to the repeated infusion of foreign proteins in factor concentrates in haemophilia therapy (the antigen overload theory) – was an important factor, as guidance on the selection of therapeutic materials was developed.

**12.44** Dr Peter Kernoff<sup>76</sup> expressed the view in the Haemophilia Society publication *The Bulletin*, edition 33, No 1, January 1983, that the links between AIDS and concentrate therapy for haemophilia were ‘very tenuous’. Haemophilia patients might be at increased risk of AIDS *if* AIDS was caused by an infectious agent and *if* this agent were transmitted in blood – ‘and these are both big “ifs”’.<sup>77</sup> The idea that there was an epidemic of AIDS amongst haemophilia patients was dismissed as ‘ludicrous’. In general, he said that AIDS was just the latest item in a long list of possible risks associated with factor therapy.

**12.45** Dr Kernoff’s views were noted in the media<sup>78</sup> and by the Department for Health and Social Security (DHSS), where it was commented that the benefits of clotting factor concentrates ‘far outweigh the possible, and as yet unproven hazards of the transmission of acquired immune deficiency syndrome’.<sup>79</sup> It was still four months before the first suspected case of AIDS in a UK haemophilia patient (see paragraph 12.69 below). Though expressed in strong terms, Dr Kernoff’s views were within the range of acceptable expert opinion in January 1983.

### *The benefits of factor concentrate therapy*

**12.46** Debate on the selection of therapeutic materials for haemophilia therapy appears to have been influenced, at least in part, by the appreciation of the considerable benefits of factor concentrate therapy already noted.

**12.47** On 4 May 1983, the Haemophilia Society distributed a letter by Professor Arthur Bloom that has been referred to in other contexts.<sup>80</sup> Professor Bloom was influential: he was Chairman of the Haemophilia Centre Directors, a senior member of the Society’s own medical advisory panel and a member of the Central Blood Laboratories Authority (CBLA). He wrote that the cause of AIDS was quite unknown and that it had not been proven to result from transmission of a specific infective agent in blood products. He too supported continuing use of current therapy using concentrates and referred explicitly to the benefits of factor concentrate therapy in support of his position:

<sup>76</sup> Director of the Haemophilia Centre at the Royal Free Hospital, London

<sup>77</sup> *The Bulletin*, Edition 33 No. 1 [PEN.016.0595] at 0605–0606

<sup>78</sup> *The Observer*, 16 January 1983 [DHF.001.7108]

<sup>79</sup> DHSS memo, ‘Factor 8 and the Observer article’ [DHF.001.7111]

<sup>80</sup> Professor Bloom’s statement to the Haemophilia Society [DHF.001.4474]. The letter is set out in full in the Preliminary Report at paragraph 8.25, and has been quoted in part and discussed in Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1* at paragraphs 9.90–9.98.

Haemophiliacs, their parents and doctors have always balanced the quality of life and the dangers from bleeding against the risks of treatment. We are no strangers to infective diseases, such as hepatitis, which can be transmitted by factor concentrates ....

....

Thus whilst it would be wrong to be complacent it would equally be counter-productive to alter our treatment programmes radically. We should avoid precipitate action and give those experts who are responsible a chance continually to assess the situation.<sup>81</sup>

### ***Imported commercial blood products in England and Wales***

**12.48** Throughout the UK at this time, practitioners were confident of the safety of the domestically produced factor concentrate products and remained confident so long as there was no evidence of infection in recipients of NHS blood products. There were significant differences between Scotland and the rest of the UK that affected discussion of risk, however, which have to be borne in mind. In particular, treatment options in England and Wales were limited by the inability of the public sector manufacturer to meet the demand for Factor VIII concentrate. Scotland had more ample supplies of concentrates manufactured at the Protein Fractionation Centre (PFC, the manufacturer of NHS blood products in Scotland) and this important distinction is explored below. In the first place, however, the position in England and Wales is discussed without reference to these differences.

**12.49** In most, if not all, regions of England and Wales, Factor VIII therapy using concentrates necessarily involved the use of imported commercial products. As noted in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, the distribution of NHS materials in England and Wales was provided for on a regional basis, with concentrates manufactured at the Blood Products Laboratory (BPL, the manufacturer of NHS blood products in England and Wales) distributed pro rata to the contributions from each region of plasma for fractionation. At all material times, NHS output was insufficient to meet total demand and the shortfall was met by commercial purchases, funded by regional health authorities.<sup>82</sup>

**12.50** In early 1983, the supply of NHS manufactured Factor VIII concentrate accounted for less than 30% of the demand in England and Wales. The remainder was commercial product, largely imported from the USA. As shown in Chapter 21, *Haemophilia Therapy – Use of Blood Products*, Figure 21.2, commercial Factor VIII was the main therapeutic product used throughout the 1980s in England and Wales and the use of imported products could not realistically be avoided if concentrate therapy was to continue.

**12.51** Dr Mark Winter described the state of affairs as he found it when he became Consultant Haematologist at Kent and Canterbury Hospital in 1983. The scope for choice of therapeutic products was limited. The output from the BPL was restricted by the capacity of the plant<sup>83</sup> and his centre obtained only small quantities of NHS Factor VIII concentrate. At least 90% of the concentrate available for use was commercial. This formed part of the practical background to his response to the emergence of the AIDS threat: whatever

<sup>81</sup> Professor Bloom's statement to the Haemophilia Society [DHF.001.4474]

<sup>82</sup> Chapter 21, *Haemophilia Therapy – Use of Blood Products*

<sup>83</sup> Dr Winter – Day 16, page 29; Dr Winter – Day 15, page 93

he thought of the risk, he could not discontinue the use of imported concentrates. In fact, Dr Winter said that he was convinced at a relatively early date that AIDS was caused by a blood-borne infective agent but, for him and for Haemophilia Directors with similar views, concentrate therapy was dependent on the products of US pharmaceutical companies. In time, the capacity of the production facilities in England was increased. The foundation of a new facility at Elstree, aimed at self-sufficiency, was laid on 23 March 1984. That was, however, clearly too late to make any impact on the importation of commercial concentrates while the threat of transmission of HIV/HTLV-III continued.

**12.52** In the circumstances, discussion in England and Wales tended to focus on the continuing use of imported products. Support for the status quo in coagulation therapy was forcefully expressed in the article by Dr Kernoff referred to above. In addition to supporting continued use of factor concentrates generally, he wrote that it would be premature to jump to the conclusion that commercial concentrates were more dangerous than NHS concentrates. In any event, dependence on US imports was a fact of life and he saw no reason to change current practice. His final comment was that:

For particular patients, and at particular centres, there may be reasons for preferring cryoprecipitate, but these reasons have little to do with AIDS.<sup>84</sup>

**12.53** For Dr Winter – even though his personal assessment of the situation at the time was different – that was an understandable position to adopt, having regard to the obvious benefits derived from the use of concentrates:

He is a very respected figure looking at the data and saying it is of concern, but we are talking about a product that has revolutionised the lives of patients and there is a major obvious benefit to this treatment. We will have to look at the risk that appears to be evolving. That was the situation of the day.<sup>85</sup>

### ***Recommendations and guidance***

**12.54** The approach of Professor Bloom, set out in his letter of 4 May 1983, was supported at a special meeting of the UK Haemophilia Reference Centre Directors. That meeting of 13 May 1983 at St Thomas's Hospital was chaired by Professor Bloom and was convened specifically to discuss the problem of AIDS.<sup>86</sup> There were noted to be ten cases of AIDS in homosexual males in the UK by that date and one haemophilia patient was reported as being 'suspected' of suffering from the disease. Concern was expressed at the definition of AIDS and it was advised that evidence of impaired cell-mediated immunity should not be regarded as necessarily leading to AIDS.<sup>87</sup> The consensus reached at that meeting among the Haemophilia Reference Centre Directors in attendance was set out in a letter from Professor Bloom to the Directors, including Scottish Directors, dated 24 June 1983.<sup>88</sup> Reflecting both the view that the aetiology of AIDS was as yet unknown and the appreciation of the benefits of concentrate therapy, he commented that, with the exception of some vulnerable patients:

<sup>84</sup> *The Bulletin* Edition 33 No. 1 [PEN.016.0595] at 0606

<sup>85</sup> Dr Winter Day 16, pages 13–14

<sup>86</sup> Minutes [DHF.001.4384]. By this time, Glasgow and Edinburgh had been recognised as Haemophilia Reference Centres, although they do not appear to have been represented at this meeting. On 8 August 1985, Glasgow and Edinburgh were described in DHSS correspondence as 'perhaps ... regarded more as centres of excellence than Reference Centres': [DHF.001.7665]

<sup>87</sup> Impaired cell-mediated immunity was not, at the time, sufficient alone to be officially regarded as a case of AIDS. See Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*, paragraphs 9.102–9.104 for the 'reporting criteria' in place at the time.

<sup>88</sup> Letter [SGH.002.2175]

It was agreed that there is as yet insufficient evidence to warrant restriction of the use of imported concentrates in other patients in view of the immense benefits of therapy but the situation will be constantly reviewed.<sup>89</sup>

**12.55** General recommendations were agreed:

- For mildly affected patients with haemophilia A or von Willebrand's disease and minor lesions, treatment with DDAVP should be considered.
- It was noted that many Directors already reserved supplies of NHS cryoprecipitate and concentrates for the treatment of children, mildly affected patients and patients unexposed to imported concentrates and the recommendations suggested that it would be 'circumspect to continue that policy.'<sup>90</sup>

**12.56** At this stage, the recommendations were less cautious in the case of Haemophilia A as compared with the NHF directives in the USA, noted in paragraph 12.30 above. The NHF recommendation was that DDAVP should be used for mildly and moderately affected haemophilia patients. In relation to concentrates, in addition to children and mildly affected patients or patients not previously exposed to imported concentrates, the NHF recommended that concentrates should not be introduced to newly-diagnosed patients or to patients with mild haemophilia.

**12.57** Additional points were made after the meeting and reported by Professor Bloom in his letter of 24 June. The first of these related to the treatment of patients with Haemophilia B. He commented:

The evidence to incriminate factor IX concentrates in AIDS is even less than with FVIII and it seems logical to continue to use our normal supplies of NHS concentrate.<sup>91</sup>

**12.58** That remained the consensus view throughout the development of the AIDS crisis and it was only later that a small number of AIDS cases came to be reported in Haemophilia B patients.<sup>92</sup>

**12.59** Opinion on therapy was also developing in Europe. The Committee of Ministers of the Council of Europe adopted Recommendation No R(83)8 on 23 June 1983. It dealt with the prevention of the spread of AIDS as a result of infected blood donations. It recommended that Member States:

[T]ake all necessary steps and measures with respect to the Acquired Immune Deficiency Syndrome and in particular:

- To avoid wherever possible the use of coagulation factor products derived from large plasma pools; this is especially important for those countries where self-sufficiency in the production of such products has not yet been achieved;
- To inform attending physicians and selected recipients, such as haemophiliacs, of the potential hazard of haemotherapy and the possibility of minimising those risks.<sup>93</sup>

<sup>93</sup> Recommendation No. R (83) 8 of the Committee of Ministers to Member States [DHF.001.4550]

**12.60** The first recommendation would have restricted the use of factor concentrates manufactured in the UK as well as imported commercial products. The qualification regarding self-sufficiency would have affected England and Wales to a greater extent than Scotland, which was closer to self-sufficiency. The emphasis on large-pool products appears implicitly to have reflected the view – clearly not yet accepted by all UK haemophilia clinicians – that AIDS was spread by infected blood products, as did the emphasis on the prevention of AIDS transmission by means of blood transfusion. To that extent, it presented a challenge to those who disagreed with the Committee of Ministers to explain their position.

**12.61** In May 1983, Dr Frank Boulton<sup>94</sup> wrote to Professor Bloom.<sup>95</sup> Professor Bloom replied on 23 May and commented:

We have not laid down hard and fast regulations since the detail of treatment will depend upon local circumstances. I do not think that anyone is complacent about the situation but I think that we all agree that it would be counter-productive to ban the importation of blood products at this moment ... The Haemophilia Society have expressed concern that we are not expanding the home treatment programme with sufficient vigour ....<sup>96</sup>

**12.62** There was media comment on the views of the Haemophilia Society in the same period. On 18 May 1983 in an article with the headline 'US Gay Blood Plague Kills Three in Britain', *The Sun* reported that the Haemophilia Society had appealed to the government not to ban US blood products.<sup>97</sup> The Society was said to have claimed that without the US imports there would be a sharp rise in the number of deaths among people with haemophilia.

**12.63** On 11 July 1983, in a note on 'Factors to be considered in the Selection of Hepatitis Reduced Products for Clinical Trial – Evaluation of Residual Infectivity for Hepatitis Viruses', Dr John Craske<sup>98</sup> commented that the possibility had to be considered that Factor VIII concentrate prepared from plasma donations obtained in the USA might be contaminated with a putative infectious agent associated with the cause of AIDS.<sup>99</sup> However, he said that there was, as yet, no product which was not made from sources which were likely to carry such a risk (implicitly accepting that, if the infective agent theory were to prove accurate, there was every reason to suppose that it would enter the UK blood supply in time, if it had not already done so). On his approach, there was not much that could be done to avoid the use of coagulation factor products derived from large plasma pools, whatever their origin.

### **Contrary views**

**12.64** There were, however, contrary views. Dr Spence Galbraith of the Communicable Disease Surveillance Centre supported a temporary ban on the use of certain imported

<sup>94</sup> Dr Boulton was Consultant in Haematology and Blood Transfusion in Edinburgh, 1980–90, and Deputy Director of the SEBTS from 1982–90.

<sup>95</sup> Dr Boulton's letter has not been found. He could not remember what his recommendations were: Day 24, pages 42–45. He thought that his concerns related to England and the growing awareness of the risks associated with blood products.

<sup>96</sup> Letter [SNF.001.3711]

<sup>98</sup> Public Health Laboratory Service (PHLS), Withington Hospital, Manchester

<sup>99</sup> Pages 3–5 of UK Haemophilia Centre Directors Hepatitis Working Party's Annual Report for the year 1982–83: Factors to be considered in the selection of hepatitis reduced products [SNF.001.0948]

products in a paper 'Action on Aids' sent to Dr Ian Field of the DHSS in May 1983. Dr Galbraith stated in his covering letter:

I have reviewed the literature and come to the conclusion that all blood products made from blood donated in the USA after 1978 should be withdrawn from use until the risk of AIDS transmission by these products has been clarified.<sup>100</sup>

**12.65** Dr Galbraith's reasoning was based on the transmissible agent theory. It was a powerful statement of the risk as perceived by a public health specialist but it did not ultimately lead to the change in policy advocated: his advice was rejected by the Biologicals Sub-Committee of the Committee on the Safety of Medicines on 13 July 1983.<sup>101</sup> It was concluded by the Sub-Committee that withdrawal of imported products was not feasible on the grounds of supply. In addition, the perceived level of risk did not 'at present justify serious consideration of such a solution'. It was anticipated that the efforts being made to secure UK independence from foreign suppliers would reduce markedly, although not eliminate, the risks to recipients. It was noted that haemophilia doctors and patients, who saw first hand the benefits of Factor VIII over cryoprecipitate, did not wish blood products from the USA to be withdrawn.<sup>102</sup> It is apparent that the Sub-Committee shared the opinions of the haemophilia clinicians and the Haemophilia Society over the crucial issue of withdrawal of imported commercial products.

**12.66** The conclusions rejecting Dr Galbraith's recommendations were controversial for some. According to evidence provided to Lord Archer, some experts were taken aback by the decision.<sup>103</sup> Professor Christopher Bartlett, formerly of the Communicable Disease Surveillance Centre (CDSC), is reported to have said, 'I was dismayed when the Sub-Committee concluded that the risk was small, because I, like Dr Galbraith, found that the evidence was rather stronger than that ....'<sup>104</sup> Dr Galbraith was 'completely bowled over' by the Sub-Committee's decision.<sup>105</sup>

**12.67** Dr Winter commented that this stage was, in his view, another highly critical time.<sup>106</sup> He thought that everything Dr Galbraith had said in his paper was true, scientifically: in retrospect, what he proposed would have saved some lives. Clinicians and those advising them were, however, constrained by concerns about the consequences of withdrawing imported concentrates. Given the risk to patients, particularly that of exposing patients to potentially fatal cerebral bleeds, Dr Galbraith's proposal would have been met with very great reluctance by doctors and by patients.

**12.68** At this stage, therefore, in the summer of 1983, Dr Galbraith, a public health specialist, favoured avoiding imported concentrates; Dr Craske, also a public health specialist, acknowledged a risk but thought it common to all Factor VIII concentrates; and the Haemophilia Society and its advisers remained committed to the use of concentrate, including imported products, though exceptions were provided for in practice guidance.

<sup>100</sup> The Inquiry team has only a very faint copy of this paper [MIS.001.0001] at 0002. A retyped version of the letter and paper is at [MIS.001.0005].

<sup>101</sup> Minutes of the Sub-Committee on Biological Products [MIS.001.0291] at 0292. Dr Galbraith was in attendance at the sub-committee as an expert adviser [DHF.002.8865]. The meeting is discussed in more detail in Chapter 9, *Knowledge of the Geographical Spread and Prevalence of HIV/AIDS 1*, at paragraph 9.106. Professor Ludlam stated that Dr Galbraith's letter was not discussed at the UKHCDO Reference Centre Directors Meeting on 13 May 1983, probably because the proceedings of the Committee on the Safety of Medicines were confidential – Day 19, page 35.

### *First AIDS deaths in the United Kingdom*

**12.69** By May 1983, there had been deaths in the UK from AIDS in the male homosexual community and AIDS was suspected in a haemophilia patient in Cardiff.<sup>107</sup> By 31 July 1983, 14 cases of AIDS had been reported to the CDSC.<sup>108</sup> One of the 14 was a haemophilia patient who had received Factor VIII imported from the USA.<sup>109</sup> A second case of infection in a haemophilia patient, in Bristol, had apparently not been formally reported to the CDSC by this stage. The risk from blood products imported into Britain was considered by the CDSC to be 'very small' at that time: there were about 2167 patients with haemophilia then receiving treatment in the UK, the majority with imported Factor VIII concentrate. By September there were two well documented cases of AIDS in haemophilia patients in England and Wales and one had died of the disease.<sup>110</sup> These events did not, however, have an immediate or significant impact on treatment policy or practice.

**12.70** On 21 June 1983, the CBLA Central Committee for Research and Development in Blood Transfusion met for the first time. The Chairman, Dr Harold Gunson, outlined the problems caused by AIDS and noted that 'it appeared to be spread by blood and blood products'. However, the general feeling of the committee was reported to be that 'not enough was known about AIDS to enable any decisions to be made'.<sup>111</sup>

**12.71** The coordinator of the Haemophilia Society wrote to a government official on 15 August 1983 regarding a meeting arranged to take place between representatives of the Society and Lord Glenarthur, Parliamentary Under-Secretary of State, DHSS, on 8 September 1983.<sup>112</sup> The issues the Society wanted to discuss included the avoidance of banning the importation of concentrates from the USA unless there was definite evidence that this was necessary. An undated file copy of a letter from Lord Glenarthur to the Society sets out the points made at the meeting.<sup>113</sup> He commented that, in considering whether the import of blood products from the USA should cease, it was deemed necessary to weigh the possible risks of infection from AIDS against the obvious risks arising from inadequate supplies of Factor VIII.<sup>114</sup>

**12.72** On 10 September 1983, the UKHCDO surveillance of AIDS in coagulation disorder patients was updated. The 'Cardiff patient', reported in the CDSC bulletin of 6 May as a possible case of AIDS, remained reasonably well. The 'Bristol patient', however, had been unwell through June and July and died in August. This was considered to be the first confirmed case of death from AIDS in the UK associated with blood products. Both cases were reported to the Haemophilia Centre Hepatitis Working Party on 14 September 1983<sup>115</sup> and to a meeting of the Haemophilia Reference Centre Directors on 19 September 1983.<sup>116</sup>

<sup>107</sup> CDSC Report for week ending 6 May 1983.

<sup>113</sup> Letter DHF.001.4573]

<sup>114</sup> At the meeting of the Biological Sub Committee of the CSM on 13 July, it had been commented that concentrates from the USA to be used in the UK should be derived from plasma complying with the new FDA regulations of 23 March 1983, provided supply could be assured. See [DHF.002.8865] at 8866.

<sup>115</sup> Minutes of the 12th Meeting of the UK Haemophilia Centre Directors' Hepatitis Working Party held at the Oxford Haemophilia Centre on 14 September 1983 [LOT.003.5434]

<sup>116</sup> Minutes [LOT.003.2862]

**12.73** The UKHCDO Hepatitis Working Party report for 1982–83 was produced on 28 September 1983 under the chairmanship of Dr Craske.<sup>117</sup> It commented on the possible contamination of plasma by a putative AIDS-related agent as a complication. It reflected the views Dr Craske had previously expressed that, at that stage, the existence of an infective AIDS agent was considered to be unproven but, if an infective agent existed, all source material might be infected by it, as was the case for the non-A, non-B Hepatitis virus. The dilemma for clinicians prescribing therapy was expressed but not resolved.

**12.74** On 17 October 1983, the UK Haemophilia Centre Directors held their 14th meeting, in Manchester.<sup>118</sup> By then, information about one of the haemophilia patients, treated in Bristol, had been published in *The Guardian* and Dr Geoffrey Scott, from Bristol, attended the meeting. There was, therefore, first-hand information available about the patient who had died there, although the record does not disclose whether Dr Scott contributed to the meeting. Dr Morag Chisholm of Southampton raised the problem of patients refusing to take up commercial Factor VIII concentrate because of the AIDS scare and wondered whether they could revert to cryoprecipitate for home therapy. Other Directors voiced similar concerns. Professor Bloom replied to Dr Chisholm:
